serves as the attachment point for the femur to the pelvic girdle (Newton 1985). The ischium forms the caudal floor of the pelvis, and the pubis forms the cranial floor of the pelvis. Each hemipelvis attaches to the other on the opposite side to form the ischial and pubic symphyses (Pasquini, p. 26).

#### Pelvic Limb

The femur, fibula, tibia, metatarsal bones, tarsal bones, and phalanges make up each pelvic limb. The femur is the long bone of the hind limb and is comprised of a proximal head, neck, and greater trochanter, a shaft, and distal lateral and medial condyles (Carrier et al. 2006, p.2225). The head of the femur attaches to the pelvic girdle at the acetabular fossa via the round ligament forming the hip joint. The tibia and fibula are the hind limb bones just distal to the femur. The distal femur, proximal tibia, and patella form the knee joint. The fibula is long and slender and lies lateral to the thicker tibia bone. The ankle joint is formed by the tarsal bones. The five metatarsals and phalanges make up each foot and its digits (Pasquini, p. 26).

## Conclusion

Despite differing appearances and functions, the skeletal systems of most vertebrates have many similarities both developmentally and anatomically. The basic building blocks of the skeletal system, bone and cartilage, remain relatively consistent throughout vertebrate skeletons with few anatomical and developmental variations. The assemblage of these basic building blocks also retains a consistent theme when compared across different branches of the vertebrate phylogenetic tree. The skeletal differences that exist between species can be attributed to differing anatomical physics needed for different environmental and lifestyle needs. Despite these differences, all species' skeletal systems are an essential basic component of life providing structural foundation, support of the body's soft tissues, protection of internal organs, and necessary leverage for muscle function.

## Skinner Box

Abigail Burns<sup>1</sup>, Maddie Sparks<sup>1</sup> and David A. Washburn<sup>1,2</sup>

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

## Synonyms

Operant chamber; Operant conditioning chamber; Repeating puzzle box

As its name suggests, the “Skinner box” was invented by B. F. Skinner while he was still a graduate student at Harvard University in the 1930s. Rather than use the term “Skinner box,” Skinner only ever referred to this invention as an operant chamber or as an experimental box, space, apparatus, or chamber (Nye 1992). The origin of the “Skinner box” title has generally been associated with psychologist Clark Hull, having appeared in his publication, *Principles of Behavior: An Introduction to Behavior Theory* (Hull 1943; see also Iversen 1992). However, the term “Skinner box” appears in other publications, as early as 1939 (Krechevsky 1939; Smith and Smith 1939; Humphreys 1940).

Skinner first began studying animal behavior during his graduate training at Harvard. Inspired by the work of Pavlov, Skinner sought to study behavioral adaptation in rats using a controlled environment (Skinner 1972). He first constructed a soundproof box with a long tunnel ending in a flight of steps. Skinner described this as “something like a functional Parthenon” (1972, p. 104). As Skinner’s interests evolved, so did his devices. Over time, he became interested in rat reflexes and developed a rectangular runway to study reflex responses. As he observed the rats, he was intrigued by their delayed behavioral responses.

As his interests shifted to the rate of response, he created a new recording system to track the rate of behavioral change over time, and the runway morphed into a recognizable Skinner box (Skinner 1972). It has been described as a “repeating puzzle box” (Washburn et al. 2017), in that, like Thorndike’s classic puzzle box (or problem box) apparatus, it afforded the opportunity to study how an animal’s behavior was changed by the consequences of the animal’s previous actions (i.e., by the Law of Effect); unlike the Thorndike puzzle box, however, the Skinner box permitted repeated and automated testing without manual resetting of the trials or manual recording of the responses.

Skinner first described the “experimental box” that would bear his name on pages 48–51 and in Fig. 1 (reproduced below) of his classic book *The Behavior of Organisms* (Skinner 1938; see also Heron and Skinner 1939). The apparatus consisted of a small, sound-attenuating box containing a lever (or, in subsequent versions, a disk for pecking) that the animal could interact with and a delivery mechanism for food or another reinforcer (Nye 1992). The technique used to create these food pellets was quite detailed, involving the mixing, shaping, hardening, cutting, and delivery

of a palatable reinforcers in such a way that allowed the pellets to enter the box unhindered (Siegel 1944). The apparatus was integral to Skinner’s systematic studies on the behavior of rats and provided a simple, unambiguous, and standardized operant behavior (i.e., lever pressing) that was within the spontaneous exploratory repertoire of rats (or that could be established quickly through shaping, or reinforcement of successive approximations), but that is a low-frequency behavior prior to conditioning. The operant chambers also provided discriminative stimuli, such as the presence or absence of the bar or a light that could be illuminated or dimmed to signal the availability of reinforcement. These discriminative stimuli allowed for the study of stimulus control of behavior. Skinner (1938, pp. 59–60) described the cumulative recorder that he used to make a record of each subject’s rate of responding over time (see also O’Donohue and Ferguson 2001) and the ways in which response rate changed as a function of the schedule of reinforcement. Thus, the operant-conditioning chamber provided Skinner with a controlled environment in which he could examine the conditions that affected the rate of response in rats and, subsequently in other animals, principally pigeons (Nye 1992). With this device, Skinner was

FIGURE 1

#### A TYPICAL EXPERIMENTAL BOX

One side has been cut away to show the part occupied by the animal. The space behind the panel at the left contains the rest of the lever, the food magazine, and other pieces of apparatus.

able to study variables that affected the rate of instrumental behavior, controlling the contributions of other potential discriminative forces (O'Donohue and Ferguson 2001).

Whereas Skinner primarily used rats and pigeons (the latter reinforced with brief intervals of access to grain for pecking a disk within the apparatus) as subjects in his operant chamber, subsequent research quickly adapted the paradigm for use with larger mammals (Rutherford 2009, p. 46). For example, Smith and Smith (1939) studied the effects of water deprivation in cats using a version of what they called a "Skinner box" and documented extinction curves that differed from those Skinner found with his rats. In the 1950s and 1960s, psychologists went even further, creating operant chambers for humans, for example, for testing children with autism (Ferster and DeMyer 1962) or adult in-patients with schizophrenia (Skinner et al. 1954). However, these Skinner boxes should not be confused with the infant "air crib" that Skinner developed for the comfort, not the conditioning, of his own daughter (Joyce and Faye 2010).

With operant chambers available from commercial manufacturers, the Skinner box became a standard testing paradigm for behavioral research with animals – particularly rats and pigeons, which in turn became the primary laboratory animals studied by psychologists (Beach 1950). In spite of Skinner's desire that the apparatus not be eponymous, psychological publications specifically using the term "Skinner box" grew tremendously in the literature. A PsycInfo and Google Scholar search reveals approximately 500 articles published in the 1950s with specific mention of the term "Skinner box," and this number approximately tripled to around 1,500 per 10-year period for each remaining decade of the century. Whereas researchers using the operant chamber were willing to alter its physical details to fit the specificities of whatever species or phenomenon they were studying, such apparatus were typically described a "modified Skinner box" rather than some new instrument (e.g., Ferster 1953; Flick et al. 2011; Kaye and Cox 1965). In the first two decades of the twenty-first century, the number of publications that including

the term "Skinner box" has continued to grow. Relatively few of those publications are new empirical reports employing the apparatus (e.g., PsycInfo shows fewer than 100 publications since 2000 with "Skinner box" in the title or abstract, and the number remains below 500 publications when "operant chamber" and synonyms are added as a search term). In this relative trickle of empirical publications using the Skinner box, many are focused on the effects and implications of drug administration or use (e.g., Sanchis-Segura and Spanagel 2006). Nevertheless, the use of the term "Skinner box" remains common in publications, whether through descriptions of continued refinements (e.g., Pineño 2014; Sokolowski et al. 2010) or in general discussions operant conditioning, used either literally (e.g., Rutherford 2009; Weizmann 2005) or metaphorically (e.g., Abernathy 2014; du Boulay 2019). The popularity of the Skinner box was also not limited to the United States. For example, a Skinner box for pigeons was shipped in 1952 to Keio University in Japan at the request of Professor M. Yokoyama where its use reached beyond operant conditioning into comparative psychology more broadly (Sakagami and Lattal 2016).

The emergence of personal computer technology had conflicting effects on the widespread use of operant chambers. On the one hand, computer technology provided for more powerful control of experimental manipulations and data recording than the highly reliable but limited electromechanical control units and cumulative recorders that were commercially available for Skinner boxes (e.g., Crossman 1984; Crossman and Williams 1978; Kamil and Sacks 1972; Nichols and Potter 1982). On the other hand, computers would ultimately become a rival apparatus for studying operant behavior, either by replacing the animal – as with the popular "virtual rat" software that allowed students to learn about operant conditioning without live animals (Graham et al. 1994) – or by replacing the operant behavior itself. Touchscreen technology gave researchers the opportunity to replace lever-pressing for the rat or disk-pecking for the pigeon with responses directly to the computer screen (e.g., Gibson et al. 2004; Markham et al. 1996; Brown and Morrison 1990; Wright

et al. 1988). The light and other simple discriminative stimuli of the Skinner box were replaced with the infinite computer-generated stimulus variety that could be presented on the touchscreen. In spite of the declining number of studies using the box itself, the Skinner box's prevalence in the literature continues as it stands as a foundational development in the study of operant conditioning.

Although Skinner's box quickly became popular in the field of psychology, his work with the box also generated great controversy over the years. Some authors have criticized Skinner for excluding previous psychological research on behavior and the basing of his entire theory on his own research with rats (Krechevsky 1939). Others took issue with Skinner's generalization from research with rats to the understanding of behavior of humans or of other animals (e.g., Beach 1950; Nye 1992). Despite these critiques, it is undeniable that Skinner's box has made critical and extensive contributions to the field of psychology (Washburn et al. 1994).

Perhaps the greatest impact of Skinner's operant chamber is the research which has generated from it that has moved beyond the use of a physical chamber. The operant chamber allowed researchers to isolate the phenomenon of operant conditioning and study it in a systematic, empirical fashion. From this solid base, psychologists began applying their knowledge of operant conditioning in real-world situations from classrooms to psychiatric wards (Rutherford 2009). The impact of the Skinner box has reached far beyond Skinner's initial research and continues to influence how we view operant conditioning and behavior today.

## What Is Sleep?

All animals sleep (Campbell and Tobler 1984; Cirelli and Tononi 2008). All undergo periods of rest, accompanied by reduced responsiveness to external stimuli, that if prevented continuously is detrimental to the body, ultimately leading to death. Sleep might be one of a few essential features shared across the animal kingdom. The search for the function of sleep is not as obscure as a few decades ago, and several functions have been identified showing that animals critically depend on a period of sleep.

## Definition and Criteria

Sleep is a complex phenomenon and is thus defined by multiple criteria (Table 1). Sleep is a rapidly reversible state of reduced responsiveness, typically accompanied by immobility and a characteristic posture. Sleep is distinguished from quiet wakefulness by the reduced ability to respond to stimuli and from coma or hibernation by its reversibility (Cirelli and Tononi 2008). Sleep is homeostatically regulated: Loss of sleep leads to an increase in sleep pressure and is compensated by a sleep rebound, which consists of an increase in sleep duration and quality (i.e., increased deep sleep as well as reduced sleep fragmentation). In most species, sleep is timed by the circadian clock appropriate to their

ecological niche but occurs as well in the absence of a circadian enforcer (Zeitgeber). Like hunger or thirst, sleep is elementary to an organism, as it cannot be evaded and its absence leads to death.

In addition to the essential criteria above, sleep changes during the lifetime with respect to its duration, timing, and number of sleep bouts. A remarkable example can be found among honey bees (*Apis mellifera*), where sleep duration and timing change extremely during the lifetime and thus between castes. As worker bees age, they take different working positions in their hive (castes): While young “cell cleaners” sleep generally longer, without 24 h rhythmicity and inside the cell, aged foragers sleep less, yet in clear day-night rhythmicity and usually outside the cell (Klein et al. 2008). During early development, sleep is elevated and becomes more fragmented as organisms age. Stimulants and hypnotics can modulate sleep in all model organisms studied, and sleep seems to be accompanied by similar changes in gene expression across different model organisms (Table 2, Cirelli and Tononi 2008). Sleep is not to be confused with hibernation and torpor, which are states of reduced metabolism. In fact, Arctic ground squirrels (*Spermophilus parryii*) wake up from hibernation in order to sleep (Daan et al. 1991). Only among mammals and birds sleep is mainly defined using electroencephalographic (EEG) criteria, while in other animals, sleep is evaluated behaviorally (Hartse 2011). In any case, EEG alone is insufficient to distinguish sleep from wakefulness.

**Sleep, Table 1** Criteria for sleep

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

## Measuring Sleep

In mammals sleep is mainly divided into two states: rapid eye movement (REM) sleep, based on saccadic movements of the eyes, and non-rapid eye movement (NREM) sleep. While NREM sleep can be well distinguished from wakefulness based on EEG alone, the EEG during REM sleep resembles wakefulness. Therefore, the gold standard for measuring sleep in humans is polysomnography, which includes EEG, electrooculogram (EOG) to detect movement of the eyes, and electromyogram (EMG) to detect muscle atonia.

**Sleep, Table 2** Properties of sleep across the animal kingdom

|           | Increased arousal threshold | Sleep rebound | Body posture | Twitches | Increased during development | Change in gene expression | Stimulants Hypnotics | Melatonin | Memory function | SWS Deep sleep | REM Active sleep |

Note: All animal models studied express an increased arousal threshold during sleep and a specific body posture. Twitches are often apparent during sleep. After sleep deprivation, there is a homeostatically driven rebound in sleep (increased sleep duration and/or intensity). Sleep is increased during early development and triggers changes in gene expressions compared to wakefulness. Sleep is affected by stimulants and hypnotics. Melatonin is found in all model organisms tested so far. Sleep modulates memory function. Only in mammals and birds distinct phases of sleep (SWS and REM sleep) are found. However, other animals show distinct deep sleep phases. Green check mark, sign is found in animal model; red cross, sign is not found in the animal model; question mark, studies diverge on this question; bar, sign has not been studied so far in the respective animal model

Often an electrocardiogram (ECG) to detect sleep stage-specific fluctuations in heart rate is recorded, as well as measures of body temperature and airflow (Carskadon and Dement 2011, Maski et al. 2011). For studies in rodents, sleep scoring is mainly based on EEG and EMG, accompanied sometimes by video analysis. A typical setup in mice would comprise two frontal and two occipital EEG electrodes as well as two EMG electrodes applied to neck muscles (Oyanedel, March 2017, personal communication).

Although time consuming, detailed video analysis can provide a good estimate of the total sleep time and an approximation on the portion of different sleep phases. Typical behaviors include:

- Ritualized pre-sleep behavior such as grooming, place cleaning, nest building, circling (getting positioned to a sleep posture), yawning, and social sleep calls (Blumberg and Rattenborg 2017).
- Typical body postures with the head and neck bend in a certain position (remarkable examples are seen during REM sleep in the giraffe and the flamingo) as well as feet grabbing or bending in a certain way (Hartse 2011; Sicks 2012).
- Typical body changes during sleep like movements of the eyes, ears, or whiskers, while the eyes are usually closed.
- Rhythmic and arrhythmic periodical body twitches, sometimes even body shaking.

While during REM sleep muscle twitches commonly occur, NREM sleep in mice might include periods of shaking (Blumberg and Rattenborg 2017).

- Changes in heart rate as sometimes externally visible: NREM is accompanied by reduced heart rate and breathing movements with further reduction in REM. Heart rate might fluctuate strongly during phasic REM as seen in mice.

In insects such as flies and bees, sleep is associated with an overall decrease in brain activity as measured by local field potential recordings (Nitz et al. 2002). Yet, in invertebrates, sleep is mainly evaluated behaviorally: in *Drosophila* by infrared beam crossing (which is rather unspecific, Hendricks et al. 2000) and recently by video evaluation. For example, sleep in bees and cockroaches (*Blaberus giganteus*) has been measured by video analysis of the antennae that cease movement completely during deep sleep phases (Tobler and Neuner-Jehle 1992; Zwaka et al. 2015). Ants fold their antennae during deep sleep, while mandibles and glossae are retracted. One group reported rapid antennal movement during deep sleep (RAM sleep) in the fire ant (*Solenopsis invicta*) (Cassill et al. 2009). In *Drosophila* and cockroaches, deep sleep is accompanied by a distinct postural change: After 10 min of immobility, the head position becomes more supported, closer to, or even resting on the surface, while the rest of the body is relaxed, exhibiting only respiratory movements (Hendricks et al. 2000). As seen in mammals, *Drosophila* spend more time within this deep sleep phase after a night of no or little sleep (van Alphen et al. 2013). This is an indicator that this deep sleep phase might play a comparable role to the one seen in mammals.

## Why Animals Sleep so Differently

### Sleep Duration and Sleep Structure Across the Animal Kingdom

“Nothing in biology makes sense except in the light of evolution” – Dobzhansky, (1973). Daily

sleep in mammals can range from 3 h in the horse or donkey to 20 h in the armadillo. There is no singular factor, such as brain size, that determines the amount of sleep an animal requires (Capellini et al. 2008; Lesku et al. 2005). The great differences in the time of day chosen for sleep, total sleep duration, sleep fragmentation (sleep that is monophasic or polyphasic), and proportion of time spent in the different sleep stages depend largely on the ecological niche. Determining factors are:

- Nutrition: Herbivores have to spend more time in search and consumption of low caloric food, and carnivores such as cats have little predation risk and consume high caloric food.
- Position in the food chain (predator or prey): Prey minimizes sleep time in order to reduce their risk to predation (Lima et al. 2005).
- Restrictions of habitat: REM sleep is incompatible with swimming in aquatic mammals or flying in continuously flying birds (Blumberg and Rattenborg 2017).
- Temperature of the surrounding.
- Rate of metabolism.
- Animal size: Smaller mammalian species tend to sleep polyphasically.
- Relative brain size (i.e., brain size adjusted to body mass): Potentially reflects differences in cognitive abilities between species (Capellini et al. 2008).

Sleep is always a trade-off with other activities. In male pectoral sandpipers (*Calidris melanotos*), for instance, those that sleep the least during mating seasons have the greatest reproductive success (Aulsebrook et al. 2016). White-crowned sparrows (*Zonotrichia leucophrys gambelii*) can reduce their sleep by over 60% for weeks during the migratory season (Lesku et al. 2005). Great frigate birds (*Fregata minor*) reduce their sleep by 92% while flying continuously over the ocean for up to 10 days hunting but spend ~50% of their time sleeping while on land. Generally, sleep can be suppressed for certain periods but usually not without serious health consequences. Interspecific variation in sleep duration can as well be compensated though the intensity of sleep (Tobler 1995).

**Sleep, Fig. 1** Sleep in mammals is divided mainly into two stages: non-rapid eye movement sleep (NREM sleep) which comprises slow-wave sleep (SWS) and rapid eye movement sleep (REM). During SWS high amplitude slow-wave activity is observable in the EEG in the 0.5–4.0 Hz range that can be accompanied by spindle

activity in the 12–15 Hz band. Spindles often co-occur with sharp-wave ripples in the hippocampus, forming so-called spindle-ripple events that play a role in memory consolidation. REM sleep comprises low-amplitude mixed frequency as well as theta activity in the EEG (Adapted from Vorster and Born (2015))

Quantifying specific sleep times for each individual species in order to gain comparable data is challenging, and may not even be feasible. Reported sleep durations and proportion of sleep states depend on both intrinsic and methodological factors, such as (i) age of the animal; (ii) season in regard to light period, temperature, mating, and migration; (iii) whether observation occurs in captivity or the wild; (iv) sleeping alone or in the group, especially in social living animals; (v) food availability, (vi) health status; and (vii) recording type (e.g., video, EEG, or infrared beam, Aulsebrook et al. 2016; Capellini et al. 2008). Therefore, sleep times reported in different studies vary to a great extent. Indeed, there is great variability within individual species, which affects accuracy of surveys using small sample sizes in particular. In that sense, comparable data between animals is rather scarce. Only a minority of animals have been studied in depth in terms of sleep.

### On the Function of REM and NREM Sleep

Sleep among mammals and birds is mainly divided in NREM (quiet sleep) and REM sleep

(active sleep, paradoxical sleep). In humans, NREM sleep can be further divided into four stages, with stages 3 and 4 further specified as slow-wave sleep (SWS, deep or delta sleep; Fig. 1). In animals apart from humans, SWS is often used synonymously with NREM sleep. During NREM sleep, limbs relax, eyelids close, eyes are still, and breathing slows. SWS is determined by high amplitude slow oscillatory EEG activity in the 0.5–4.0 Hz frequency band and spindle activity in the 12–15 Hz band (only in mammals). Sleep spindles are characterized by a waxing and waning 12–15 Hz pattern of oscillatory activity in the cortex driven by the thalamus (Fig. 1) and play a role in memory consolidation (Buzsaki et al. 2013). Slow-wave activity is based on the synchronous brief silencing of cortical neurons firing, just like an applauding audience occasionally synchronizes its clapping, generating a clap that is overall louder and better heard. The brief cortical silence within such a slow wave is followed by a quick re-depolarization of the cortical neurons that is thought to facilitate the generation of spindle activity originating from thalamic networks.

There are two types of REM sleep: tonic and phasic. Tonic REM sleep is driven by the parasympathetic nervous system with low heart rate and no eye movements, while phasic REM sleep is driven by the sympathetic nervous system with co-occurrence of rapid eye movements, muscle twitches, and fluctuating respiration. During REM sleep, muscle tone is suppressed (muscle paralysis, muscle atonia), forcing most animals to stop any movement and to lie down and relax. Furthermore, the ability to regulate body temperature is reduced.

REM sleep is often accompanied by jerky twitches of the limbs, digits, and eyes that might bear great functional significance (Blumberg and Rattenborg 2017). Unlike NREM sleep, during REM sleep, the connectivity within the brain, especially the neocortex, is high. This increased cortical connectivity during REM sleep results in desynchronized brain activity of low-amplitude mixed frequency and theta activity (4–10 Hz) in the EEG signal with relatively higher power in the high-frequency ranges. The exact function of theta activity is to date unclear; it is merely a hallmark of REM sleep.

Sleep in mammals and birds consists of several cycles of REM and NREM sleep, and sleep usually starts with a period of NREM sleep. The first half of nocturnal sleep is dominated in most mammals by NREM with little REM sleep, whereas the second half of the night is dominated by REM sleep. REM sleep is controlled, at least in part, by

the endogenous circadian clock, while SWS during NREM is driven by homeostatic sleep pressure, that is, by the increasing propensity to sleep with respect to the amount of time spent awake (Tobler 1995). As sleep pressure decreases during the night, the amount of SWS decreases, while the amount of REM increases with progressing time of the day. A common idea is that the physiological differences of these two sleep stages reflect functional differences. The duration of single REM and SWS episodes differs greatly among species: In humans SWS periods typically last for up to 40 min at the beginning of the night and 5 min toward the end, and REM sleep bouts for 5 min at the beginning of the night and 20 min toward the end (Carskadon and Dement 2011). In rodents SWS (termed NREM) episodes last from 60 to 300 s, while REM sleep episodes last about 100 s. In pigeons (*Columba livia*), periods of SWS last around 50 s at the beginning of the sleep period and decrease to 25 s toward the end. REM in birds accounts for less than 10% of the total sleep time distributed in very short epochs of 4–8 s. Thus the functional mechanism of REM and NREM sleep is not ultimately tied to the duration and fragmentation seen in the different species (Table 3).

Slow-wave activity is driven by intrinsic cortical activity as well as through the thalamus. The six-layered cortex in mammals is not a prerequisite for the existence of SWS, as birds have a rather nuclear brain structure instead of a six-

**Sleep, Table 3** Sleep and sleep state duration in different animal models

|        | Total sleep time (min) | Total REM (min) | Total NREM (min)           | Average duration SWS epoch (s) | Average duration REM epoch (s) | Cycle duration (min) |
|--------|------------------------|-----------------|----------------------------|--------------------------------|--------------------------------|----------------------|
| Human  | 400–500                | 150             | 50–150 (SWS)<br>340 (NREM) | 300–1800                       | 300–1200                       | 90–120               |
| Mice   | 600–800                | 150             | 500                        | 300–500                        | 40–100                         | 5–10                 |
| Rat    | 440–800                | 80              | 360                        | 100–200                        | 100                            | 5–10                 |
| Pigeon | 300–500                | 25              | 400                        | 20–50                          | 4–8                            | 1–5                  |

Note: While the total sleep time (24-h period) in humans, rodents, and birds is rather consistent, the average duration of slow-wave sleep (SWS) or rapid eye movement (REM) sleep epochs vary greatly and so the duration for one sleep cycle comprising SWS and REM sleep. All data given for the different animals are approximations and might vary substantially depending on recording type, age, and exact species. (Carskadon and Dement 2011, Oyaneldel personal communication, March, 2017, Martinez-Gonzalez et al. 2008)

layered cortex and still express SWS. Even in primary cortical cell culture, after several days, synchronized rhythmic on-off bursting activity appears. This “sleep in a dish” model resembles to some extent sleep on the molecular level (Hinnard et al. 2012). Slow-wave activity can occur locally, while the rest of the brain is more in a wakeful state, so termed “local sleep.” The presence of local sleep during a motor task is associated with lapses in performance. Further, using a specific brain region to solve or complete a task during wakefulness leads to increased slow-wave activity in that same brain area during subsequent sleep. To some extent, this is evidence that slow-wave activity originates in higher brain regions independently of the thalamus, which drives slow-wave activity as well. Thus, the thalamus is not the only driver of the slow-wave activity. It however tunes and coordinates slow-wave activity in the cortex.

Sleep deprivation in all mammals and birds leads to a sleep rebound, especially of SWS (Tobler 2005). The amount of SWS is therefore a good indicator of the sleep pressure or sleep need. NREM sleep is the state through which torpor and hibernation are entered. However, animals that awake from hibernation spend increased time in NREM sleep. In fact hibernating animals interrupt hibernation periodically to spend most of their time sleeping in SWS (Daan et al. 1991). More importantly most of the energy spent during a period of hibernation is invested in these interruptions.

### The Ecological Niche Shapes Sleep

NREM sleep allows for stereotypic behavior as seen in migrating birds that sleep unihemispherically (occurring only in half of the brain) while continuously flying for several days and ruminating animals that chew on their food while sleeping. Sleepwalking in humans takes place during SWS as well. SWS can be unihemispheric in most birds and marine mammals (whales, dolphins, sea cows, walruses, and sea lions), while REM sleep cannot (Tobler 1995). Still, birds prefer to rest with both hemispheres, and both eyes closed, especially when in a safe location or surrounded by members of the colony.

Marine animals show little to no REM sleep. The accompanying muscle atonia appears to be incompatible with an aquatic lifestyle that supposedly requires permanent motion (Blumberg and Rattenborg 2017).

REM but not NREM sleep is decreased in species under high predation risk (Lima et al. 2005). The reason for this observation might be attributed to the muscle atonia during REM sleep that forces animals to lie down, which is an especially vulnerable position, especially among horses and giraffes (Sicks 2012). In altricial mammals, those that are born immature, REM sleep declines strongly from birth to adulthood, whereas in precocial animals, REM sleep quanta and the duration and proportion of sleep stages are stable throughout life (Blumberg and Rattenborg 2017). This might give us some clues on the function of sleep with respect to brain maturation during development. Because REM sleep is accompanied by reduced thermoregulation, researchers suggested that REM sleep is reminiscent of reptilian (poikilotherms) wakefulness (Lesku et al. 2005). Diverging ambient temperatures during sleep reduces REM sleep in rodents, possibly because of the incapacity to regulate the body temperature during REM sleep (Amici et al. 2008; Lesku et al. 2005).

### Current Hypotheses on the Function of Sleep

There are several hypotheses on the functions of sleep that are based on substantial evidence. Most certainly they all convene in one framework of sleep. During evolution different body processes might have allocated to the time of natural inactivity (Blumberg and Rattenborg 2017). The question is which core function of sleep initiated the development of a period of inactivity and reduced responsiveness. Alternatively it is possible that rest periods always existed in all forms of life due to sun-dependent (circadian) change in food availability and temperature, allowing different metabolic processes to be most efficiently performed at certain time windows.

**Sleep for Memory Consolidation: Active System Consolidation Theory**

At first our memories are usually episodic (Diekelmann and Born 2010). We recognize the different aspects of an event, such as what, where, and when something happened, without drawing final generalized conclusions. Only with time our brain compares, associates, and integrates our new memories with existing ones. Then we are left with the gist of our memories and encounters. We mostly forget exactly when, where, and with whom we met and often retain only the conclusions drawn from an important encounter without knowing the exact location and the exact content of our conversation.

The active system consolidation theory claims that during wakefulness, information is rapidly

encoded first into an initial store, in mammals the hippocampus (Fig. 2). Due to the reactivation of those memories during sleep, the information becomes gradually redistributed and dependent on other areas of their long-term storage; in mammals this involves the cortex and striatal areas. In this way, new memories are integrated into the existing context of memories and thus become decontextualized and schema-like (gist extraction). In support for this hypothesis is the finding that hippocampal-dependent memories, mainly declarative memories, benefit from SWS (Blumberg and Rattenborg 2017; Diekelmann and Born 2010). Further, sleep facilitates the insight into underlying rules and structures. It seems that during sleep newly acquired memories are reviewed and commonalities are drawn. Thus,

**Sleep, Fig. 2** Active system memory consolidation in different species. (a) In humans new episodic memories are initially stored and/or triggered by the hippocampus (orange). During slow-wave sleep (SWS), memories are reactivated and presumably redistributed by means of spindle-ripple events toward the long-term store residing mainly in the neocortex (green) leading to a de-contextualization of the memories. (b) Imprinting

memory in chicks is initially encoded in the left IMM (intermediate and medial mesopallium). Presumably during SWS, the imprinting memory is redistributed to a yet unknown locus S', again accompanied by a transformation of the memory in that way that it can be more flexible applied to different contexts (The location of S' is presently unknown therefore the actual placement of S' in the figure is meaningless.) (Adapted from Vorster and Born (2015))

sleep permits implicit memory to become explicit thereby qualitatively transforming memories.

Sleep spindles seem to play an important role in memory formation. For instance, the density of sleep spindles increases after a declarative learning task compared to a non-learning control task. During the slow-oscillation upstates, which occur during SWS, so-called spindle-ripple events are detectable, during which hippocampal ripples are nested into the excitable troughs of sleep spindles (Buzsaki et al. 2013). These spindle-ripple events provide a mode of communication between the hippocampus and the cortex and striatal regions. Ripples trigger the replay of CA1 (cornu ammonis area 1) place cell firing patterns in the hippocampus that also occurred during prior waking periods. Some milliseconds after ripples occur in the hippocampus, assembly reactivations are detectable in neocortical and striatal areas. Blocking sharp-wave ripples after learning reduces memory consolidation. Enhancing spindle activity via acoustic stimulation during sleep and concomitantly stimulating slow oscillations increases memory consolidation in humans. Triggering reactivations during sleep via an odor that was also present during training enhances exclusively the consolidation of the odor-connected memories (Vorster and Born 2015).

A deficit of active system consolidation theory is that it makes no prediction on the function of REM sleep as it is arranged around the different hallmarks of NREM sleep: cortical slow waves, sleep spindles, and hippocampal ripple activity (Diekelmann and Born 2010; Vorster and Born 2015).

### **Sleep for Synaptic Tuning: Synaptic Homeostasis Hypothesis (SHY)**

Wakefulness and learning trigger an increase in synaptic strength and cortical excitability (Cirelli and Tononi 2008). The chance of epileptic seizures, for instance, increases after long periods of wakefulness. Repeatedly increasing synaptic strength is unsustainable and fatal for a nervous system as it demands more room, requires higher energy consumption and demand for cellular supplies, and decreases signal-to-noise ratio, which can all lead to a

fatal instability of the nervous system. The firing rate of neurons within a nervous system is finely tuned: just enough background activity to allow for communication but as sparsely as necessary, since the brain is already the most energetically costly organ (in humans, comprises 20–30% of the body's energy expenditure). Therefore, any change in connectivity (learning) must be balanced out with a change in synaptic strength at another place in the system.

The synaptic homeostasis hypothesis claims that sleep serves exactly this purpose: The homeostatic regulation of the nervous system occurs through renormalization of net synaptic strength and restoration of cellular homeostasis while the brain is disconnected from external intrusions (Joiner 2016). According to this hypothesis, slow waves during SWS serve to globally downscale and renormalize synaptic potentiation. Yet so far slow waves during sleep have been found only in mammals and birds. The theory is compatible with the increased sleep need during development, a period of great neuronal rewiring and plasticity. In humans, the quanta of REM and NREM sleep change in accordance with different steps during brain maturation. One of the simplest organisms known to exhibit signs of sleep, the nematode *C. elegans*, sleeps only after developmental-induced times of quiescence, named lethargus. A great number of key genes are regulated during lethargus in *C. elegans* in the same manner as during sleep in *Drosophila*, mice, and humans.

### **Sleep for Metabolic Clearance**

Sleep promotes the removal of neurotoxic waste that accumulates during wakefulness. In a seminal study in mice, sleep led to a 60% increase in interstitial space and thus allowed for quicker exchange of cerebrospinal fluid, also leading to increased rates of  $\beta$ -amyloid clearance (Xie et al. 2013). The hypothesis is supported by the finding that in mammals the ratio of cortical neuron density to surface area is positively correlated with the total sleep duration (Herculano-Houzel 2015). Higher neuronal density relative to the surface area of the brain demands for an increased clearance time (sleep). Thus, a longer sleep time is

needed to allow for a complete flush of metabolic waste products.

### Sleep for Energy Conservation

The energy conservation theory claims that sleep functions to reduce energy expenditure at times that cannot be efficiently used for other activities. From all the hypotheses debated, this is the most unlikely one (Capellini et al. 2008). The energy savings during sleep is only 10–20%. During sleep there is a change in the *type* of neuronal activity but not in the amount of activity. Most importantly this hypothesis does not explain why we lose consciousness, become less responsive to hazardous stimuli, and cannot postpone sleep especially during dangerous situations (while driving a car for instance). Just to save 20% of energy? This theory especially does not explain REM sleep, during which cortical EEG resembles wakefulness. In contrast to NREM, REM is a sleep state without energy savings with respect to brain activity but with the deficit of reduced responsiveness to external sensory information. Overall, the slight energy savings during sleep appears to be rather an energetic adaptation of the body to an obligatory sleep period.

### Sleep for Immune Function

The immune system largely depends on sleep. Chronic and partial sleep deprivation lead to deficits in immune function and host defense mechanisms. Cytokines such as tumor necrosis factor alpha (TNF alpha) and interleukin-1 beta (IL-1β) are induced by sleep (Joiner 2016). Both cytokines are released in response to infections as well as through sleep deprivation. SWS promotes the interaction between antigen-presenting cells and T cells that store the antigenic information for the long term (Westermann et al. 2015). Sleep especially eases the extravasation of T cells and their redistribution to lymph nodes. After a vaccination, sleep, especially SWS, doubled the frequency of antigen-specific T helper cells. More importantly, the specific T helper cell response continues to be stronger even after one year in a group that was allowed to sleep the night following vaccination in comparison to a group that was sleep deprived. A night of sleep after

vaccination thus leads to a stronger and longer-lasting protection (Westermann et al. 2015). The immune system does not reasonably demand for the loss of consciousness or a loss of responsiveness during sleep. Therefore, it seems more likely that certain immune processes shifted to coincide with the sleep period to fulfill its functions.

## What Drives Sleep?: The Molecular Basis of Sleep

### GABA Promotes Sleep

Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter. GABAergic agonists promote sleep (Joiner 2016). In mammals GABA is released from the ventral preoptic area (VLPO, Fig. 3b) and inhibits wake-promoting areas. Most sedatives target GABA<sub>A</sub> receptors (benzodiazepines and non-benzodiazepine drugs with similar effects (Z-drugs) as well as ethanol). GABA<sub>A</sub> receptors reduce excitability and promote sleep in numerous animals (flies, zebra fish, and mice). However, sedation is not to be confused with natural sleep! To date no real sleep-inducing remedy is known.

### Biogenic Amines Such as Histamine Promote Wakefulness

In mammals a number of neurotransmitters promote wakefulness. Among these are norepinephrine (noradrenaline, in flies named octopamine), serotonin, dopamine, and histamine (Saper et al. 2005; Joiner 2016). For example, the first generation of antihistamines leads to increased drowsiness as a side effect, as they antagonized the wake-promoting function of histamine in the brain. Stimulants such as amphetamines, modafinil, and methylphenidate (Ritalin) are dopamine reuptake inhibitors, increasing the persistence of dopamine in the synaptic cleft. All of these transmitters are found in other model organisms such as flies and fish and somehow interact with sleep. Octopamine and dopamine are wake promoting in flies; however, serotonin seems to be sleep promoting in flies. In humans serotonin seems to have diverse functions in REM and NREM sleep. During REM and NREM sleep,

**Sleep, Fig. 3** Flip-flop switch for sleep-wake transitions in mammals. (a) While awake monoaminergic neurons in the forebrain (locus coeruleus (LC), tuberomammillary nucleus (TMN), in red) and raphe nuclei (raphe)) inhibit sleep-promoting GABAergic neurons in the ventrolateral preoptic nucleus (VLPO, in blue) and extended VLPO (eVLPO) through noradrenergic (NA) and serotonergic (5-HT) connections. (b) During sleep the VLPO inhibits

these same regions through GABAergic inhibition (GABA) forming a sharp yet unstable self-reinforcing loop that avoids transitional states. For stability the activity of wake-promoting monoaminergic neurons (LC, TMN, raphe) is reinforced through orexin (ORX) released by the perifornical area (PeF, in green) (Figure based on Saper et al. (2005))

aminergic signaling is reduced, however only during REM sleep cholinergic signaling persists to excite the cortex, explaining partly the difference between the two sleep states.

### Orexin Stabilizes Wakefulness

It is a necessity for an organism that the whole brain undergoes sleep and wakefulness in a coordinated manner. If this was not the case, groups of neurons would go independently to sleep, resulting in many islands of local sleep intruding wakefulness and thus negatively affecting performance. Besides, some functions proposed by the active system consolidation theory demand that the whole brain undergo sleep (e.g., sharp-wave ripples riding on slow waves in mammals and birds). Further, wakefulness has to be stabilized in a way that the brain does not suddenly flip back

to sleep during a potentially dangerous motor task, as seen in narcoleptic patients.

During wakefulness monoaminergic neurons in the forebrain (locus coeruleus, tuberomammillary nucleus, and raphe nuclei) inhibit GABAergic neurons (sleep promoting) in the ventrolateral preoptic nucleus (VLPO). In return, during sleep the VLPO inhibits these same regions. This way activity in one region shuts down inhibitory activity in the other region and thus strengthens its own action. This self-reinforcing neural loop serves to be a sharp switch as it avoids transitional states yet is rather unstable. For stability during wakefulness, the activity of awake-promoting monoaminergic neurons is reinforced through orexin released by the perifornical area (Saper et al. 2005, Fig. 3). Humans and dogs with narcolepsy lack orexin-producing neurons and

therefore often flip during wakefulness to REM sleep, especially if not fully rested. Recently, a functional analog of vertebrate orexin (FLP-2) and the receptor (FRPR-18) was found in *C. elegans* that promotes pigment-dispersing factor 1 (PDF-1) secretion and vice versa (Chen et al. 2016). In flies, the pigment-dispersing factor might have an analogous function as orexin and is found in the central clock neurons.

### **Melatonin: The Molecular Clock**

The hormone melatonin is expressed in evolutionary distant species like dinoflagellates and is universally used as a molecular clock. Melatonin is degraded by a light-sensitive reaction, possibly serving as a light-protecting pigment as it is a free radical scavenger. Melatonin is produced at all times but degrades during the day, and thus peaks in all organisms during the night. However, melatonin is by far no sleep hormone! While humans and birds sleep at night and melatonin signals the time to sleep, in nocturnally active rodents, melatonin signals activity and wakefulness.

### **cAMP and CREB: Learning and Sleep Are Molecularly Linked**

The conserved core pathway of learning known in all animals from worms to humans includes the second messenger cyclic adenosine monophosphate (cAMP), the protein kinase A (PKA), and the cAMP response element-binding protein (CREB). Increased signaling of cAMP and CREB activity is associated with waking as found in flies and rats (Mackiewicz et al. 2008). Increased sleep after being exposed to an enriched environment (as seen in flies) depends on cAMP, possibly due to memory consolidation processes. The up- or downregulation of the transcription regulator CREB always affects the amount of waking and sleep. Increased CREB activity occurs during rebound sleep after sleep deprivation.

### **The Adenosine Hypothesis: Cellular Activity Induces Sleep**

The most traded pharmacological agent – caffeine – promotes wakefulness. Caffeine promotes

wakefulness in flies, mice, and humans, yet its pathway of action is still debated. The mode of action in mammals is hypothesized as follows: During wakefulness ATP is converted to adenosine and released by neurons as a co-transmitter, raising extracellular levels of adenosine and signaling the body a need for sleep (Joiner 2016). Caffeine binds reversely to the adenosine A<sub>2A</sub> receptor and hinders adenosine from binding and activating the receptor and thus suppressing the sleep-promoting signal. Administration of adenosine or adenosine A<sub>1</sub> receptor agonists induces sleep by inhibiting wake-active neurons, while A<sub>2A</sub> receptors activate sleep-active neurons. However, in flies caffeine acts rather on the cAMP pathway than on the adenosine receptor, promoting wakefulness globally in the brain without restrictions to a specific brain region.

### **Conclusion**

A major part of life is devoted to sleep in all organisms, pointing to an essential and evolutionary ancient function. Sleep is finely adjusted to the ecological niche of each species. Ecological conditions determine whether an animal sleeps in monophasic or polyphasic fashion, during day or night, and for long or short duration. Clear signs of REM sleep and NREM are only found in mammals and birds. However even invertebrates show particular phases of deep sleep. “Sleep is of the brain, by the brain and for the brain” as Allan Hobson (2005) once put it. Cognitive deficits are the first effects of sleep loss. The current two main hypotheses of sleep, the active system consolidation and the synaptic homeostasis hypothesis, are focused on memory function. Yet, during evolution other vital body functions like the immune system took advantage of sleep, allocating certain processes to that period of rest. The same sleep-regulating neurotransmitters (GABA, noradrenaline), the same molecular pathways (adenosine signaling, learning cascade including CREB), and the same molecular clock (melatonin) are

shared among all animals pointing once again to a shared vital function of sleep.

[Plasmodial slime molds](#)

## Definition

Acellular mass of amoeboid cells containing large number of spore.

## Introduction

Slime molds are single cell eukaryotic fungus-like protists collectively form multicellular reproductive structures and classified as fungi. It has been stated that more than 900 species of slime mold discovered all over the world and named “slime” due to their appearing as gelatinous. It is highly prominent organisms appear on mulch (*Fuligo septic*, bright in color spread over soil surface) (Zhulidov et al. 2002), plants, and grass (*Physarum*) magically and also called

as “blob” or “dog vomit fungus.” There are 700 types of slime molds are found in nature with the different shape, structure, and color. Slime molds. The slime molds growing on mulch are bright in color (yellow, orange, bluish-gray, purple-brown, and creamy), unequal mass, and different in diameter (1 inch to several feet). In lawns, the presence of a slime mold gives the grass a bluish-gray to purple-brown appearance from a distance. These areas can be patchy and can be as large as several feet in diameter. Basically, they appear on that portion of plants which are closest to soil ground such as woody and herbaceous plants. Some colorful slime molds have been reported on the lower branches of juniper or rhododendron. Slime molds can causes indirect injury to the plant besides of being pathogenic. They shade and cover the plants to slow down photosynthesis. The macroscopic slime molds mostly lie in myxogastria. The size of slime molds is few centimeters or up to several square meters and 30 g of masses (Zhulidov et al. 2002). Some “cellular” slime molds do not spend most of their time in this state. During shortage of food, many single-celled organisms aggregate and start moving as a single body. Aggregation state of slime molds is very sensitive to airborne chemicals and can detect food sources. They can change the shape to produce fruiting bodies and release many spores and through wind due to having lightweight (Jacobson 2012). Slime molds (*Stemonitis*, *Physarum polycephalum*, *Fuligo*, etc.) behave as saprophytic and feed on bacteria, yeasts, and fungi to contribute in decomposition of dead vegetation. Slime molds usually occur in soil, lawns, and on the forest floor, commonly on deciduous logs. In tropical areas, slime molds are commonly found on inflorescences and fruits, and in the canopy of trees. The drier environmental conditions are always unfavorable for the slime molds and transform into shapeless plasmodium to sporangium (organized structure). For their growth, cool, shady, and moist conditions are always favorable for slime molds. Though, they can readily grow in the sunny area which indicated that temperature and moisture are the main

important factors connected with their presence and occurrence. Since past 10 years they associated with patterns of weather and increased the popularity of woody mulches.

## Taxonomy of Slime Molds

According to older classification, slime molds are polyphyletic and placed in the subkingdom Gymnomycota in the Fungi kingdom including phyla Myxomycota, Acrasiomycota, and Labyrinthulomycota (Worley et al. 1979). Recently, slime molds have been divided into several supergroups other than kingdom Fungi. Slime molds are divided into two main groups: (1) Plasmodial (single membrane without walls) e.g., *Dictyosteliida* and (2) protists (unicellular). The modern classification comprises the slime molds in the mycetozoa group of the amoebozoa which includes three groups Myxogastria, Dictyosteliida, and Protosteloids (intermediate between Myxogastria and Dictyosteliida) (Baldauf and Doolittle 1997). Slime molds are divided into two categories: true slime molds and cellular slime molds (Farr 1981). True slime molds lies under Myxomycota (plasmodials) and Dictyosteliomycota considered as cellular slime molds (Nakagaki 2001; Keller and Braun 1999; Steven and Stempen 1994; Raper 1984). The slime molds grow in the moist (well-rotten logs) environment and eats bacteria for their survival. Because of the presence of delicate fruiting bodies, it appear as fungi (Wang 2015; Herron et al. 2013). They are small in size (1 or 2 mm) and therefore difficult to recognize. The slime molds of myxomycete groups are resembles as plasmodium (two amoeba-like cells fused together to form a formless, growing mass) (Adl et al. 2005). Plasmodia are pale, cream, gray, bright yellow, or orange in color. It engulf its food mainly bacteria as the same way as amoeba eats their food. The myxomycetes are multinucleate globule of protoplasm lacking cell wall. Cell membrane is the only structure which keeps everything in. They ingest bacteria using pseudopodia, which is also known as “false feet,” this process is known as phagocytosis followed by

digestion. In case of true fungi, the food digestion always found before the ingestion process. The formation of fruiting bodies always takes place during harsh environmental condition and lacking of food. Several dormant and resistive spores produce by fruiting bodies, which further germinate into uninucleate myxamoebae. These uninucleate myxamoebae later fuse to form a plasmodium through mitotic division to complete their life cycle. The cellular slime molds (*Dictyosteliomycota*) are multicellular, which is also considered as social amoebae lacking of true plasmodium. Under food scarcity, they produce some chemical signals to neighbor amoebae (<http://www.wisc.edu/botany/fungi/volkmyco.html>). The *Dictyosteliomycota* create a fascinating challenge in evolutionary theory by showing altruistic behavior. They sacrifice their reproductive potential for the transportation to a new more food location to grow again. Some non-amoebozoan slime molds are *Acrasids*, *Plasmodiophorids*, *Labyrinthulomycota*, and *Fonticula* (Brown et al. 2009).

## Life Cycle of Slime Molds

The slime molds feed on bacteria and start their life cycle as amoeboid like cells, having haploid single nucleus. Life cycle of slime molds comprises different stages (Fig. 1). Under favorable (moist) condition, these slime molds convert into biflagellated swarming cells by binary fission. Under scarcity of food or in unfavorable condition, they form cysts which are tough-coated cells. These amoebae form zygotes if they meet the correct mating type and grow into plasmodia. After mitosis, the diploid cells form large cells with two nuclei. In the absence of cell division, nuclei divides continuously to form multinucleated plasmodium referred as “supercell.” The supercell plasmodium migrates about 1 cm per hour as like amoeba. The slime molds change their behavior during shortage of food availability. It migrates to the favorable place and form fruiting bodies or sporangia (Alexopoulos et al. 1996). Slime molds may transform into several shapes like shapeless blobs to delicate lacy structures.

### Slime Molds, Fig. 1 Life cycle of slime mould.

There are different stages have been reported in life cycle of slime molds  
 (a) Free-living, haploid amoebae (b) Aggregation  
 (c) Formation of mound  
 (d) Appearance of the finger like tip section  
 (e) Appearance of “Mexican hat” stage  
 (f, g) Culmination  
 (h) Development and maturation of fruiting body  
 (i) Spores dispersion

During their life cycle, spores become dry and released into the air. Spores germinate into either new amoebae or form biflagellate swarming cells in the presence of water (Baldauf and Doolittle 1997). These cells are haploid in nature and serve as gametes to initiate the diploid plasmodial stage of the life cycle (Fig. 1). Under unfavorable (dry) conditions, the diploid plasmodia undergoes resting stage and start growing again when moist conditions available.

### Role of Slime Molds in Animal Cognition and Behavior

The slime mold (*Physarum polycephalum*) is an organism which resembles as blob-like and creeping giant cell (Adamatzky and Jones 2010). The biologist of Research Centre on Animal Cognition reported that slime molds have no brain but it can response and learn from experiences (Reid et al. 2012). Slime mold have tendency to reunite after physical separation. In some studies, it has been proven that slime mold like *Physarum polycephalum* has ability to find out periodic inauspicious conditions (Nakagaki 2001; Tero et al. 2010; Saigusa et al. 2008). According to Kitta (2010), behavior of slime molds is equal to the brain of animals that posses muscle and nerves (Kitta 2010). In some experiments, it has been stated that slime molds avoids light and get stimulated, and spread their plasmodia and create some thin networks to focus on resourcefully connected branches (Tero et al. 2010). The natural habitat of slime mold (*Physarum polycephalum*) is a forest litter but also can be grown in laboratory. It has been revealed that around 2000 slime mold can acquire the behavior to avoid salt (Vogel and Dussutour 2016). Some slime molds species are parasitic to aquatic invertebrates like nematodes, rotifers, diatoms and arthropods. Some other parasitic water molds may grow on other organisms like amphibians, fish scales and on their eggs. The *Saprolegnia* a water mold target the especially sick fishes to cause lesions. The organisms which are parasitic to flowering plants get affected by the slime molds and cause greater impact on human beings. The slime molds affect the some crops like lettuce, grapes, cabbage, corn,

avocados, pineapples, potatoes, etc. by causing diseases by damaging stem and leaf tissues. A very common water mold species (*Phytophthora infestans*) is responsible for the causing late blight disease in potato plants and also infect the tubers (edible part of potato). In Ireland, most of the poor people depends upon the potato which was a very important crop plants for them. In the late nineteenth century, the potato crops were infected by *Phytophthora infestans* and caused the great famine by wiping out Irish potato crops. During this famine, most of the Irish people starved to death and nearly million people emigrated to Canada and America. In the late 1870s, Downy mildew of grapes was introduced accidentally from America to Europe and wiped out entire French wine industry. The industry have used the *Bordeaux mixture* (mixture of lime and copper sulfate) save the plants to control the diseases. Use of *Bordeaux mixture* has been introduced as an important fungicide, which can be used to control a plant disease.

It has been discussed that slime molds are not able to cause pathogenesis in plants so there is no any protective control strategy is required. Control of slime mold using chemicals can create more trouble. Some chemicals can be used to permanently kill the slime molds, but the toxic applicants may create more harmful condition to the life around the slime mold. Slime molds develop on mulch can be removed with scooping or disturbed by scratching. When the slime molds appear on plants and grass or turf, a forceful water spray with a hose pipe can be used to control or remove. Mowing can be used for the removal of slime molds from the turf effectively. On the other hand, after some time, slime molds will ultimately dry up if they are left alone, which turns into powdery form and disappear.

### Conclusions

The study of slime molds has revealed that these organisms to be not just a mass of slime on the forest floor but very charismatic organisms that are able to solve mazes, modeling city planning. Not only do slime molds play an integral part of our ecology but their social behavior also provides

important insight into the inner workings of communication, movement, and altruism. At least in biology, slime molds are truly extraordinary. The fungus-like protists are unicellular. They were originally called fungi because they produce sporangia. These protists differ from fungi in that their cell walls have cellulose rather than chitin. Fungus-like protists also generally do not have divisions between their cells like fungi do. Slime molds have both animal and plant like characteristics although they themselves are not closely related to each other. Most of their lives are spent as microscopic amoebas, roaming independently through the forest feeding on organic matter, bacteria, and other microscopic morsels. During food shortages, slime molds swarm and aggregate into an enormous single cell, where they can then form fruiting bodies and release spores (Herron et al. 2013; Baldauf et al. 2000). When food (normally bacteria) is readily available for cellular slime mold, they take the form of individual amoebae, which feed and divide normally. However, when the food supply runs low, they aggregate to form a multicellular unit. The cells in the slug remain separate from each other, unlike the cells of plasmodial slime mold. The plasmodium of slime molds are heterotrophic, and they phagocytose food particles. Water molds are decomposers and break down dead matter.

## Small Interfering RNA (siRNA)

Joe C. Bague

Neurobiology, University of Pittsburgh,  
Pittsburgh, PA, USA

### Synonyms

Short interfering RNA

### Definition

Small interfering RNAs (siRNAs) are short (~20 nucleotides) RNA sequences that prevent the translation of specific genes by degrading messenger RNA (mRNA) using RNA interference (RNAi).

### Introduction

Small interfering ribonucleic acids (siRNAs) are a class of small RNA molecules that activate the RISC (RNA-induced silencing complex) pathway to degrade mRNA and prevent the synthesis of proteins (translation). The biological functions of siRNA are to protect genomic integrity from invasive nucleic acids, such as viruses, and to shape chromosome structure.

The discovery of small interfering RNAs' (siRNAs') ability to regulate gene expression is among one of the most significant advances in biology in recent years. Fire et al. (1998) were the first to discover that double-stranded RNA (dsRNA) produced a greater silencing effect than single-stranded RNA alone, arguing for the activation of an RNAi process to produce a viral resistance. It is now known that viruses produce dsRNA particles, which activate the RNAi machinery to silence genes. This landmark manuscript earned Fire and Mello the 2006 Nobel Prize and began a new field of research in RNAi. Since then, siRNA has been found in a multitude of eukaryotes, including fungi, plants, and animals.

In addition to its biological importance, there has been immense interest in developing siRNA

for use in research and therapeutics. Genomic manipulation through artificial siRNA (Elbashir et al. 2001) was the next big step in developing RNAi tools. For the past two decades, siRNA has been widely used to study gene function (in vivo and in vitro) and has been utilized as a therapeutic reagent for the treatment of diseases, most notably cancer.

### Structure

Initially, the siRNA begins as a dsRNA or small hairpin RNA. Following cleavage, by the dsRNA-specific endoribonuclease dicer, the result is an siRNA duplex (~21 base pairs) with phosphorylated 5' and hydroxylated 3' ends, which overhang ~2 nucleotides (Chen et al. 2008; Elbashir et al. 2001).

### Mechanism

Ribosomes in the cytoplasm translate mRNA particles to form long polypeptide chains, which later fold to make proteins. However, if siRNA is present, it will degrade mRNA through RNAi, thereby reducing mRNA transcripts and producing a silencing effect. The mRNA degradation process is facilitated by activating the posttranslational gene silencing mechanism RISC (Pratt and MacRae 2009). The mechanisms used to control RISC are quite diverse and species-dependent but rely on two common themes: (1) binding of siRNA to an Argonaute family protein (Ago) and (2) the guiding of RISC to mRNA for degradation.

dsRNA induces sequence-specific posttranscriptional gene silencing. First, the endoribonuclease dicer excises long dsRNA into siRNA duplexes. With the help of the transactivation response RNA binding protein, dicer helps load the antisense siRNA strand (guide strand complementary to mRNA) onto the catalytically active Ago to form the RISC assembly. This guide strand is "chosen" based on the thermodynamic asymmetry of the siRNA duplex, a phenomenon referred to as the asymmetry rule. The thermodynamically less stable 5' end of the guide strand is loaded into a specific Ago

(depending on the structure of the siRNA) and assembled into the RISC complex (Pratt and MacRae 2009). The remaining passenger strand is then discarded. There are many Ago proteins that mediate a range of functions from genome stability to suppressing translation (Okamura et al. 2004). The functionality of the siRNA is largely dependent on its structure and which Ago it's loaded into.

The single-stranded siRNA then guides the associated RISC to bind and then cleave specific mRNA. One quality of siRNA-targeted mRNA degradation is the near-perfect complementary base pairing between the siRNA sequence and the target mRNA. Once the guided RISC has found a complementary sequence, the catalytically active Ago breaks the mRNA, via mRNA hydrolysis, between positions 10 and 11 of the guide strand (Zamore et al. 2000). Once broken, mRNA degradation begins, and the guided RISC can be reused for several cycles.

## Research Tools

siRNA has been an invaluable tool for studying gene function and combating cancer; however, there are limitations and challenges when using siRNA in a laboratory or clinical setting. siRNA provides a temporary knockdown (a partial loss of a targeted gene transcripts) after infusion. This temporary knockdown can be an advantage when using RNAi technology; however, the temporary knockdown effects are not feasible for long-term experiments. Another challenge to researchers and clinicians alike is delivering the siRNA into the target cell. For siRNA to silence effectively, it must enter the cell and be incorporated into RISC. As siRNA is extremely large and too hydrophobic to pass through the lipid bilayer of the membrane unassisted, modifying the siRNA structure or assisting with the delivery is essential for its uptake into the cell. The delivery most useful for therapeutic intervention is systemic infusion; however, doing so via systemic infusion provides even more barriers as the siRNA must overcome endogenous nucleases, immune system targeting, rapid renal filtration, non-specific interactions, and entering the correct cell to knockdown the gene of interest (Tatiparti et al. 2017). There are currently

three major classes of intracellular delivery for nucleic acids.

**Chemical transfection**, which delivers nucleic acid through the lipid bilayer using nanoparticle-, polymer-, or liposome-based transfection technologies (Kanasty et al. 2013). Reagents such as cationic lipids and polymers are used to form complexes with the negatively charged nucleic acid, which are then taken up by the cell via endocytosis. These methods are advantageous because of the high efficiency of siRNA delivery and commercial availability; however, not all cell types work with this type of transfection, and this method has a low in vivo efficiency.

**Physical transfection** uses mechanical or electrical means to open the cell membrane and deliver nucleic acids. Mechanical methods include the use of ballistic, magnetic, and micro-injection transfection of siRNA particles into the cell (Tatiparti et al. 2017); however, these methods require highly specialized setups and training. In contrast, electroporation-mediated delivery is a powerful and versatile method for the delivery of small RNA into cells and tissues. This technique applies high-intensity electrical pulses to transiently destabilize the cell membrane and allow nucleic acids to enter. Cellular parameters, physiological conditions, and electrical properties determine the efficiency of delivery.

**Transduction** utilizes viral-mediated transfection methods to introduce nucleic acids into cells. The major difference between non-viral transfection and viral transfection is that viral transfection must enter the nucleus for expression (non-viral transfection does not). The most common viruses utilized in this process are adeno-associated virus and lentivirus, which are highly efficient and easy to use. The major drawbacks to using this type of transfection are immunogenicity, off-target effects, and size limitations. These consequences are the reasons why much effort has been placed into non-viral transfection methods (Kim and Eberwine 2010).

## Off-Target Effects of siRNA Therapies

Off-target effects occur when delivered siRNA has unintended consequences on gene regulation. Downregulation of unintended genes can occur if

the siRNA binds with partial sequence specificity. Typically, this occurs when the off-target mRNA is partially complementary to the siRNA seed region (position 2–8 from the 5' end of the antisense strand). These off-target effects are similar to how microRNAs regulate gene function. Scientists have many ways to reduce off-target effects, including changing the siRNA sequence and reducing the siRNA concentration. Other unintended off-target effects can occur if the immune system is triggered or if the siRNA delivery system becomes toxic for the cell. For example, protein-nucleic acid complexes have potentially high immunogenicity and, with repeat doses, can accumulate and lead to toxicity (Wittrup and Lieberman 2015).

## Conclusion

siRNA is a biological mechanism which protects genome stability from invasive nucleic acids and has proven to be a powerful tool in research and therapeutics. Since its discovery, there have been major advances to siRNA-mediated gene silencing technology. By exploiting the cells internal biology, artificial siRNA can knockdown specific genes and be engineered to avoid off-target effects and immune responses. While these advances have pushed the boundaries of gene silencing, gene editing technologies have recently become popular. Further development of siRNA-related technology would benefit research and therapeutics, but last major obstacle to overcome is the development of an efficient delivery system for siRNA.

### Synonyms

[Covert copulator](#); [Extra-pair copulation](#); [Sneak copulator](#); [Sneaker males](#); [Sneakers](#); [Sneaky mating](#)

### Definition

An individual performing copulatory behavior while withholding information about the sexual event (e.g., visual or auditory) for bystanders that could possibly prevent or disrupt the copulation.

## Introduction

From an evolutionary viewpoint reproduction is one of the most important goals of every living being. Evolutionary theory predicts that all organisms strive to have as much surviving offspring as possible. Therefore, animals have developed behaviors that increase their chances of reproduction. Because the number of available mating partners is not infinite, sexual competition is highly prevalent in animals. Animals have developed strategies to increase their chances in the competition for mating opportunities. Although many different mating systems exist across animal species, strategies for increasing mating opportunities are often similar across mating systems. There are often individual differences in strength and power between males or females. A widespread behavior that is often used by strong or powerful individuals is to monopolize copulations. Monopolization may be achieved by behaviors such as mate guarding defending a territory with copulation partners or punishing others that (attempt to) copulate. An alternative strategy, which is more often used by less strong or less powerful individuals, is sneaky copulation; by concealing sexual behavior, sneak copulators evade mate guarding and/or punishment.

## Monopolization, Mate Guarding, and Punishment

Monopolization occurs when one individual is in a position that allows it to restrict the number of copulations performed by competitors. This position may be a dominant individual which has a generally acknowledged hierarchical position which enforces others to restrict copulatory behavior in its presence (Overduin-de Vries et al. 2013). In these hierarchical systems, there is an alpha individual, usually a male (but there are also harem mating systems with an alpha female leader), which has a lot of power because he/she has proven to be the strongest, or he/she is born in the right family. Monopolization may be achieved by the mere presence of a socially dominant or physically stronger individual. This occurs when

lower-ranking or physically weaker individuals abrupt their mating attempts upon confrontation with a possible monopolizer, in order to prevent harmful conflicts. A generally used tactic by monopolizers is mate guarding; following and defending (a) particular (fertile) opposite sex individual (s). In socially monogamous species individuals follow their partner around and prevent it from copulating with others. Likewise dominant individuals in social groups mate guard fertile individuals. Mate guarding is most effective in species where the fertile phase is detectable for the opposite sex, because this limits the time frame in which mate guarding is necessary. Besides, in social groups ovulation synchrony impedes monopolization since monopolizers cannot mate guard all fertile individuals simultaneously. Another monopolizing tactic is to use aggression in order to force others to give up their copulation attempt (e.g., Gouzoules 1974). For example, monkey females that attempt to copulate with males other than the alpha male face punishment in the form of being chased, being threatened, or receiving physical aggression. Both the female and the male sneaky copulator risk punishment in monkeys. After disruption, the alpha male often copulates with the interrupted female.

## Mating Systems Including Sneaky Copulators

Sneak copulation occurs in mating systems where individuals are restricted in choosing their mating partners, e.g., in systems where monopolization or mate guarding occurs or where sexual behavior is punished by certain individuals. These are systems with pair bonds, systems where mating occurs within fixed groups and harem groups.

Monogamous pair bonding is common across the animal kingdom, especially among birds (93% of species) (Lack 1968) and primates (12% is monogamous) (Rutberg 1983). However after close inspection of sneaky behavior and DNA comparisons of parent offspring combinations, it becomes clear that much less species are also

sexually monogamous (Griffith et al. 2002). Extra-pair copulations are often the result of sneak copulators that conceals its copulations for its partner. Examples of species that are known for their strict social monogamy but that are nonetheless sneak copulators are Lar Gibbons (*Hylobates lar*) (Reichard 1995), zebra finches (*Taeniopygia guttata*) (Houtman 1992), and beavers (*Castor canadensis*) (Crawford et al. 2008).

Sneaky copulation also occurs in animal species where mating is restricted within small groups. For example, dunnocks live in monogamous couples or in small groups where two or three males cooperatively defend a territory with one or multiple females. The most dominant male intensively guards the female (s) throughout the mating season, but especially when food is scattered and the female home range expands, monopolization is difficult (Davies and Hartley 1996). The subordinate male(s) almost always fertilize some of the eggs. This is not only the result of the pursue of the subordinate males but also of the female, which actively attempts to sneak away from the dominant male to have mating opportunities with the subordinate males.

Many species such as elephant seals (de Bruyn et al. 2011), bighorn sheep (Hogg 1987), and long-tailed macaques (Overduin-de Vries et al. 2013) live in harem groups. The power of the group leader gives him/her exclusive right to copulate with the opposite sex group members. For example, elephant seal males risk their live in injurious fights with sharply teathed opponents. The winner of these fights will become the leader of dozens or even hundreds of females. However, an alternative mating tactic exists that creates opportunities for siring offspring for individuals that prefer to stay clear of risky competition: sneak copulation at sea (de Bruyn et al. 2011). This sneak copulator tactic may be particularly worthwhile for individuals that are less likely to win male-male fights. Similarly, bighorn sheep live in harem groups where one alpha male monopolizes the majority of fertile females, by mate guarding (Hogg 1987). However, females occasionally

run away from their monopolizer and sneak copulators profit by courting them and copulating quickly away from the group leader (Hogg 1987).

success of both strategies, monopolizing or sneaking, depends on the status of the male and the frequency of males and females and their strategies (Gross 1996).

## Conflict between and within the Sexes

The existence of sneak copulation within a species is often the result of a conflict between or within the sexes. Sneak copulation can be a strategy that has evolved as a female strategy within the framework of the conflict between the sexes (Parker 2006) but also as a male strategy to outcompete other males. There are different things at stake for males and females in a mating market. When producing offspring, females generally invest more than males in terms of larger gametes and the extra burden of gravidity (Clutton-Brock 1991). Therefore, females generally prefer polygamous mating which allows them to select the better sperm for their costly egg. Exceptions to this preference are often related to paternal care. If paternal care significantly contributes to the survival of offspring, females may benefit more from a single copulation partner that cares for their offspring (Gubernick and Teferi 2000), than from multiple partners that are not taking care of the offspring. However, the most successful strategy for females would be to profit from a male's paternal investment while sneakily copulating with other males in order to improve the genetic quality of their offspring (Kempnaers et al. 1992).

Males, on the other hand, have developed strategies to prevent parental investment in offspring that is sired by their neighbors. For example, monopolization of females is a strategy that limits paternity uncertainty. However, some males are better in monopolizing females than others. Whereas strong and/or powerful males profit most from monopolizing females, weaker and/or less powerful males are less likely to win contests over females and have a higher risk of injury during these contests. Therefore, alternative reproductive strategies exist for males (Gross 1996) such as sneak copulation. The relative

## Withholding Information

Sneak copulators conceal their copulations by withholding information from possible eavesdroppers, which could possibly disrupt or prevent their copulation. They withhold either visual or auditory information or both. For example, long-tailed macaques prefer to copulate near opaque structures blocking the view of a possible audience. Likewise, they copulate more often when the group leader is in a visually separated enclosure (Overduin-de Vries et al. 2013). This way they prevent possible competitors from seeing the copulation, minimizing the possibility of being disrupted during copulation.

Another way of concealing copulation is by suppressing copulation calls (Townsend et al. 2008, Clay and Zuberbuhler 2011). Low-ranking female chimpanzees (*Pan troglodytes schweinfurthii*) suppress copulation calls when high-ranking females are present. This way, low-ranking females avoid female-female competition, which can be severe in this species.

Another form of sneak copulation for males is mimicking a female. These fake females can sneak within the territory of another male or approach another male's partner without being attacked by him and perform sneaky copulation. When employing the mimic tactic, males conceal their true color during the approach of the female, withholding information about their identity, being a male.

## Cognitive Level

Withholding information from another individual is sometimes interpreted as higher-order cognition under the term deception, but it does not need to be. By using simple rules of thumb, such as "freeze behavior or change color when in close

proximity of a strong or dominant individual,” animals can conceal behavior (Amici et al. 2009) without making inferences about what another individual can see or hear. These rules of thumb can be learned by simple operant learning when sexual behavior in close proximity of dominant individuals is linked with punishment. Therefore, animals with cognitive capacities that are at least capable of learning by operant conditioning are equally likely to be sneak copulators as are more intelligent species. Moreover, mimicry is possible without operant conditioning. In some species the female mimics are inflexible traits that are genetically based (Sinervo and Lively 1996) or fixed during early development (Emlen 1997). Therefore, this tactic can be used by animals that are less cognitively advanced including fish (Dominey 1980), reptiles (Sinervo and Lively 1996), and isopods (Shuster and Wade 1991). In contrast, other mimicking species, such as the giant cuttlefish, can flexibly adjust their appearance and resemble a female when they are sneakily copulating, while they return back to male coloration afterwards (Norman et al. 1999). This flexible use of color mimicry does require cognitive processes such as operant conditioning.

## Sneaky Copulators and Human Sexual Behavior

Within human behavior, there is enough evidence that sneak copulation is a substantial contributor to the fitness of an individual. For example, women copulate more often sneakily with a lover around the time of ovulation (Gildersleeve et al. 2014). This indicates that sneak copulation is an important strategy for women to fertilize their egg with sperm other than their partners'. The rationale behind this strategy is that women try to get the best of two worlds without being aware of using this strategy. They choose a long-term partner that is caring, protecting, and a good father, while they choose strong, intelligent, high status, and good-looking lovers to fertilize their egg. There is also evidence that males have evolved counterstrategies as a response to female promiscuity (Shackelford et al. 2005). For

example, the longer a man has been away from his wife, the larger will be his ejaculate. This larger amount of sperm will give him an advance in case his sperm has to compete with sperm from another man. Moreover, there are indications that human sperm cells can selectively kill the sperm cells of rivals within the female reproductive tract (Baker and Bellis 1988). Although this theory is debated by many researchers, and convincing empirical evidence is difficult to collect, it is not the first case where sperm cells use complicated strategies to combat rival sperm (Pearcy et al. 2014).

## Social Affordance

Eros Moreira de Carvalho

Department of Philosophy, Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil

## Synonyms

Affordance; Direct perception; Ecological psychology; Environment-organism systems; Information-based approach; Perception-action theory; Social cognition; Social interaction

## Definition

Social affordances are possibilities for social interaction or possibilities for action that are shaped by social practices and norms.

## Affordance

The term “affordance” was coined by James Gibson to refer to what things or events in the environment afford to an organism. For instance, a rigid flat surface affords support and locomotion to terrestrial animals. It is stand-on-able and walk-on-able (Gibson 2015). The water surface of a lake does not afford support to a terrestrial animal, but it does to some flies. Thus, the same part of an environment may afford different things to different species or organisms. This is because affordances are relational in nature, they are both a fact of the environment and a fact of the organism. According to Gibson, affordances are neither subjective nor objective, they cut across the dichotomy of subjective-objective. There has been debate among ecological psychologists as to what in the organism is responsible for an affordance. The options range from bodily properties to dispositions to abilities (Chemero 2003). In all cases, such organismic elements are what turns a feature of the environment into a possibility for action that is meaningful to the organism.

Affordances are crucial for the ecological approach to perception. The environment shows up to an organism in terms of what it can do in it. An organism perceives by picking up environmental information that specifies the affordances of the environment. This point is crucial to understand Gibson’s approach to perception. According to the ecological approach, the environment is rich of structures and energy patterns that convey information about objects and events. Information for Gibson is a relation of specification established by lawful covariation between patterns of energy – optical, mechanical, and chemical – over time and/or space and objects or events in the environment. For instance, structured ambient light conveys information about surfaces of objects. As this information is structured over time and/or space, the organism needs to explore its environment to pick it up. Gibson explains the process of picking up information by the radio metaphor. Through exploratory movements, the organism becomes attuned to environmental information and resonates to it. Inasmuch as an organism resonates to information, it is able to

perceive affordances directly. Thus, perception is an active process that takes place over time and whose main function is to pick up information that specifies affordances.

## Social Affordance

Although Gibson did not systematize theoretically the notion of social affordances (Costall 1995), he was open to it and gave several examples of social affordances. His example of the postbox as an object that “affords letter-mailing to a letter-writing human in a community with a postal system” (Gibson 2015, p. 130) is well known. Gibson also called attention to the fact that an animal, as a self-moving being with characteristic behaviors and anatomy, affords peculiar possibilities for action to other animals. An animal “can afford eating or being eaten, copulation or fighting, nurturing or nurturance” (Gibson 2015, p. 36). Some of the latter examples, such as eating and being eaten, may not yet be considered full social affordances inasmuch as they elicit behavior in another animal but not necessarily social interaction. To have social interactions the participatory animals must have a minimal responsiveness to each other as self-moving beings and their behaviors must be mutually constrained while they are engaged in an activity. As Gibson points out, “as one moves so does the other, the one sequence of action being suited to the other in a kind of behavioral loop. All social interaction is of this sort—sexual, maternal, competitive, cooperative” (Gibson 2015, p. 36). Thus, in virtue of the coupling between the caregiver and the infant in several mammals, the caregiver affords the infant the possibility to clung and contact comfort. For species capable of joint attention, the joint perception of a predator might afford the social affordance of outnumbering our foe. Among some primates, grooming behavior affords social bonds.

The example of the postbox and the examples of social interactions point to two different senses in which the term “social affordance” is normally used. In the postbox case the letter-mailing affordance is social because it depends on an

ongoing social-cultural practice to be available. An agent from a culture without a postal system and having no idea of what a postal system is cannot perceive the postbox as affording letter-mailing. To be open to this affordance, the agent needs to be normatively responsive to and constrained by the social practice in question. In contrast to generic affordances, which can be understood in terms of the individual-object dyad, this type of social affordance requires also the social system of mutual responsibilities and conventions within which an object gains a peculiar function. In relation to social creatures like us there has been debate about whether all affordances are socially shaped in this way (Costall 1995). As to the second group of social affordances, they are social because there are possibilities for interaction that other persons or animals afford. Through these affordances a person or an animal shows up to an observer not as a physical object but as an agent with the capacity to reciprocate. These are “the richest and most elaborate affordances of the environment” (Gibson 2015, p. 126), they comprise the most basic kind of social cognition that makes cooperation and coordination possible, as well as predator–prey interactions. This type of social affordance is allegedly more fundamental since it seems to be required by the social-cultural practices that underpin the first type of social affordance.

A common criticism of the very possibility of perceiving social affordances is that there is no information about them in the environment. As the argument goes, the ambient light might contain information about objects, their surface layout, texture, and colors, but not about whether they afford, for instance, letter-mailing. The social function of an object is not perceptible. An agent comes to know that a postbox has this function only by inference. The same applies to social affordances regarding persons and animals. Possibilities for interaction are allegedly not perceptible, there is no information in the environment about whether an animal affords cooperation or aggression. An animal can see movements and facial expressions of another animal but not that it is open to and waiting for interaction. Gibson himself claims that “other

animals and other persons can only give off information about themselves insofar as they are tangible, audible, odorous, tastable, or visible” (2015, p. 127), which raises the question about whether other animals and other persons can give off perceptible information about their social affordances.

A set of considerations may help to put away the worry above. The first point to notice is that the animal’s movements, gestures, and facial expressions can be sufficiently patterned over time and/or space to specify a wide range of possibilities for interaction. By picking up such a pattern, an observer may be said to perceive directly the corresponding possibility for interaction. This, however, might not be enough to resolve all possible ambiguity. A second consideration concerns the notion of information itself. One possibility to have more information in the environment regarding social affordances is to weaken the notion of information. Instead of requiring a specifying relationship, it may be enough a probabilistic relationship between an energy pattern and a social affordance in that the former makes the presence of the latter likely (Bruineberg et al. 2019). Another alternative would be to relativize the notion of information to environments or habitats. A specifying relationship does not need to hold over all environments to make perception possible. A local specifying relationship that holds only in a specific environment might be sufficient to perception provided the perceiver dwells in that environment. Thus, optical information about the postbox might be sufficient to specify the letter-mailing affordance in a social environment where there is a postal system.

A further consideration on this issue is that the social environment should not be taken as detached from the natural environment; actually the dichotomy between nature and culture should be overcome. For many species, particularly ours, the social is a background condition not only for their evolutionary history but also for the development of their members (Heft 2007) so that a new member with cooperative dispositions enters in an environment which is already socially structured. In relation to practices within a social

environment, complex energy patterns may convey information about social affordances for beings with prosocial capabilities immersed in those practices.

Both affordances shaped by social norms and affordances for social interaction are important for ecological psychology to address the scaling-up problem – the problem of accounting for the higher-order cognition, such as planning, imagination, abstract thought, and language use based on basic cognition such as the perception of affordances. Attempts have been made to apply social affordances to explain planning (Kiverstein and Rietveld 2018). Synergies between ecological psychology and enactivism have been explored. Some argue that an enactive account of language can augment social affordances to deal with planning and distal engagement (Brancazio and Segundo-Ortin 2020). In anthropology, social affordances have been mobilized to overcome the dichotomy between nature and culture and to show how the human living world is socially structured and meaningful independently of symbolic thought (Ingold 2000).

The realm of social interactions has also been studied within ecological psychology, providing a rich repertoire of subtypes of social affordances to explain complex social behavior. One may distinguish, for instance, common affordance from joint/shared affordance. The former is the affordance of an object that may induce emergent coordination, such as the arrival of a bus awaited by many passengers. The latter is “an affordance for two or more people collectively which is not necessarily an affordance for any of them individually” (Knoblich et al. 2011, p. 63), such as a long two-handed saw that affords cutting to two people acting together but not to one acting alone. Both common and joint/shared affordances are also distinct from collective affordances. These are affordances available to collectives – groups of individuals who share an embodied social identity. For instance, during a match of football, the situation in the pitch may offer the collective affordance to play a counterattack to the recently attacked team (Weichold and Thonhauser 2020). Thus, social affordances provide a powerful

resource to explain a great variety of social interactions and how they may combine to give rise to complex cognition and behavior.

### Definition

**Social buffering** The improved recovery from aversive experiences when a social mammal is grouped with others of the same species (Davitz and Mason 1955).

### Introduction

Primates encounter a multitude of stressors in the wild, ranging from constant predation risk to food competition and aggressive interactions with conspecifics. In mammals, stress activates the hypothalamic-pituitary-adrenal (HPA) axis, which in turn stimulates the adrenal cortex and eventually results in the release of the glucocorticoid hormone cortisol, or corticosterone. In the immediate context, cortisol is adaptive because it motivates the “fight-or-flight” response on which

survival depends and enables individuals to act quickly to escape life-threatening situations. However, although it is adaptive in the short-term, cortisol is extremely damaging to the brain and body when released consistently over long-term periods. Cortisol has been linked to decreases in immune response as well as cognitive ability in humans and nonhuman primates, and high levels of consistent stress are known to promote disease in animals vying for dominance in a structured social system (McEwen and Seeman 1999). Interestingly, social mammals appear to have developed a hormonal mechanism that helps to attenuate the well-known negative physiological and psychological effects of stress. This mechanism is enabled by sociality and is known as social buffering.

## Attenuating Stress: Social Buffering Theory

In primates, sociality appears to increase longevity and reproductive success. Sociality is associated with positive effects on various diseases including blood pressure and cardiovascular reactivity in humans (Evans and Steptoe 2001; Gallo et al. 2000), and therefore appears to counter the negative effects of cortisol. To an extent, these biological benefits of sociality may be explained in part by social buffering and its resulting effect of reduced stress. Social buffering is the improved recovery from aversive experiences when a social mammal is grouped with others of the same species (Davitz and Mason 1955). This effect was initially studied in fear-conditioned rats, who were found to display less fearful behavior when in the presence of conspecifics (Davitz and Mason 1955), and in rat pups, who were found to be able to regulate maternal levels of cortisol release (Smotherman et al. 1977). Social buffering effects have since been found in nonhuman primates (Coe et al. 1978; Winslow et al. 2003), guinea pigs (Hennessy et al. 2000), and humans (Seltzer et al. 2010) and have been found to be modulated by neuropeptide hormones, early social experiences, and the social structure of a species.

## The Role of Oxytocin in Social Buffering

Social buffering appears to be modulated in part by oxytocin, a neuropeptide hormone critical to social development that also modulates stress reactivity. The function of oxytocin appears to be strongly conserved throughout evolution, as it plays similar roles in reproduction, bonding, and social behavior across vertebrates (Donaldson and Young 2008). It is released in response to a variety of behaviors, including lactation, affiliation, pain reduction, and stress reduction. In mammals, oxytocin attenuates cortisol through its action on the HPA axis. Specifically, oxytocin activates neurons in the hypothalamus and the resulting increase in oxytocin secretion from the hypothalamus then inhibits activation of the HPA axis, consequently attenuating the physiological effects of cortisol (Neumann et al. 2000; Neumann 2002). Moreover, intracerebroventricular (ICV) injection of an oxytocin-receptor antagonist has been observed to heighten HPA activity, further demonstrating the role of oxytocin in attenuating stress responses (Neumann 2002). Peripheral oxytocin also acts on the adrenal gland where it inhibits the secretion of corticosteroids, as well as the pituitary gland where it inhibits the release of ACTH (adrenocorticotrophic hormone), a hormone that triggers the production and release of cortisol by the adrenal gland (Neumann et al. 1998). Thus, oxytocin attenuates the physiological experience of stress through multiple avenues.

In addition to attenuating the physiological experience of stress, oxytocin has also been observed to alter behavioral responses to stress in primates and other mammals. Oxytocin receptor-mediated mechanisms have been found to be involved in stress-coping strategies in rats (Ebner et al. 2005), and oxytocin administered to human males during a social stressor decreases anxiety responses and increases calmness (Heinrichs et al. 2003). Further, oxytocin is a well-known motivator of social affiliation, a necessary precursor to any social buffering effects on stress. In male marmosets (*Callithrix jacchus*), administered oxytocin increases tolerance of infants as well as the inclination of males to

share food with infants (Saito and Nakamura 2011). In humans, increases in oxytocin induced by a parental figure have also been observed to lead to quicker returns to baseline levels of cortisol after experiencing social stress (Seltzer et al. 2010). Thus, social buffering is enabled in part by oxytocin, which motivates social affiliation that then leads to attenuated responses to stress through direct and indirect action on the HPA axis.

## Developmental Influences on Social Buffering

Stress systems and the HPA axis are regulated by social variables early in life and are also subjected to programming effects that regulate their activity levels in later stages of development (Hostinar et al. 2014). Consequently, social experiences in early development also play a strong role in regulating mammalian social buffering ability. Nursery-reared rhesus monkeys (*Macaca mulatta*) exhibit decreased levels of oxytocin in contrast to mother-reared monkeys and do not experience an attenuated cortisol response when paired with another individual in a stressful event (Winslow et al. 2003). Mother-reared monkeys also display a higher rate of affiliative social behavior relative to nursery-reared monkeys, thus suggesting that nursery-reared monkeys develop a deficit in their capacity to use social support in stressful situations. Thus, social buffering ability stems in part from the quality of social relationships experienced during early development. Further, this suggests that individual differences in social buffering ability are based on how the neuroendocrine system has adapted to the social environment experienced in early life. In regards to the development of the HPA axis, there is evidence for a “stress inoculation” effect, whereby brief separations from the maternal figure enable an infant to better adapt to stressful experiences later on in adulthood (Lyons et al. 1999; Parker et al. 2004). This may indicate that the HPA response in animals that have experienced some early stressors is better calibrated to handle a varying

degree of stressful challenges in a way that is less damaging to the body. In addition, early life stress buffering is also protective against elevated physiological responses to stress in adulthood (Liu et al. 1997), which suggests that early life social buffering also helps to protect against extreme and detrimental physiological responses to stress later in life. Although the most potent source of social buffering in primates is generally the maternal figure, an individual will develop the ability to receive social buffering benefits through other familiar conspecifics as they mature, including extended family members and preferred peers.

### Effects of Familiarity on Social Buffering

In primates, it is well-established that the most powerful elicitor of social buffering effects is the mother. In the absence of a maternal figure, infants can learn to rely on peers to buffer stress, but the ability of peers to buffer stress at this early stage in development is not as strong as the mothers and leads to issues with managing stress in adulthood (Suomi 1991). The ability of the maternal figure to remain a powerful buffer of stress continues at least throughout childhood development in humans. However, the strength of the relationship and level of familiarity with the caregiver is also of importance in modulating the strength of the social buffering effect in non-human primates. In titi monkeys (*Callicebus moloch*), the father is the preferred caregiver and is consequently also the most potent elicitor of the social buffering effect when compared to the mother (Hoffman et al. 1995), demonstrating the important role of experience and familiarity in social buffering. Other familial females also have some ability to socially buffer stress in infants. In squirrel monkeys (*Samiri sciureus*), stressed infants are able to be comforted to an extent by aunts, in addition to their biological mothers (Coe et al. 1978). Fear-conditioned squirrel monkeys have also shown reduced cortisol responses when exposed to shock cues in the presence of a familiar partner, demonstrating the

ability of familiar conspecifics to buffer the neuroendocrine response to stress.

As an individual matures, the ability of parental figures to buffer the HPA response to stress begins to decline, and the individual begins to rely more strongly on peers and romantic partners. In humans, parents start to lose their ability to buffer stress in their children once they begin to reach adolescence, which suggests that the child's developing brain no longer needs to rely on parental figures to protect it from the damage caused by stress (Gunnar and Hostinar 2015). Indeed, peers can serve as strong buffers to the HPA axis response to stress in humans and non-human primates. However, the ability of peers to attenuate the stress response is modulated by the strength of their bond with the stressed individual. Children who report more supportive relationships with their best friend display more rapid decreases to baseline levels of cortisol after experiencing a social stressor with that friend, relative to children who report less supportive relationships with their best friends (Calhoun et al. 2014). Social buffering potency is also contingent on bond strength in nonhuman primates, including male barbary macaques (*Macaca sylvanus*) who form enduring male-male social bonds in adulthood that are similar to human friendships. These bonds provide effective buffering against social and environmental stress (Young et al. 2014) demonstrating the ability of individuals to rely on peers for social buffering long after they have branched away from their parents.

In addition to peers, the ability to elicit social buffering in adulthood is extended to romantic partners as well, although it is uncertain when these extensions of the social buffering network develop. In humans, support from romantic partners buffers the HPA axis in males experiencing a social stressor, resulting in a decrease in the cortisol response (Heinrichs et al. 2003). Effective stress buffering by partners also occurs in monogamous nonhuman primates who form long-lasting pair-bonds. Titi monkeys are well-known for forming strong pair-bonds, and consequently experience buffering of the stress response when in the presence of their bonded

mate, relative to other primates who do not form pair-bonds such as squirrel monkeys (*Samirisciureus*, Hennessy et al. 1995).

## Social Structure and Social Buffering

Given the ability of close conspecifics to buffer stress in primates, it is not surprising that social buffering potency is also mediated by the social structure of a species. Strong differences in the number of individuals required to elicit a buffering response have been observed depending on a species' pattern of social organization. Squirrel monkeys, who live in large mixed-sex groups and interact mostly with same-sex conspecifics, experience the strongest buffering response when in the presence of multiple group members, relative to titi monkeys who live in lasting pair-bonds and experience strong buffering of the stress response when in the presence of their bonded partner (Hennessy et al. 1995). Robust buffering by a pair-bonded mate also occurs in marmosets (*Callithrix kuhli*), who form long-lasting pair-bonds and raise infants cooperatively in extended family groups (Smith et al. 1998).

In primates, social buffering is also dependent on the level of gregariousness as well as the strength of social hierarchies in a given species. For example, differences in the baseline levels of stress hormones and oxytocin are known to exist in bonnet macaques (*Macaca radiata*) and pigtail macaques (*Macaca nemestrina*), who exhibit stark differences in social structure. Bonnet macaques are highly gregarious and less hierarchical, and show minimal preferences for kin. In contrast, pigtail macaques live in strongly hierarchical social groups with consistent preferences for kin and often display aggressive behaviors. Accordingly, bonnet macaques exhibit lower basal levels of corticotropin-releasing factor (CRF), a neuropeptide hormone similar to cortisol which is also involved in the stress response, and higher basal levels of oxytocin than pigtail macaques (Rosenblum et al. 2002). This strong variation in baseline stress hormones as well as oxytocin suggests that the stress

buffering response in primates is mediated in part by behavioral factors such as social structure.

## Conclusion

The ability of an individual to buffer stress through sociality is modulated by social experiences in early development, as well as other variables including familiarity with peers, romantic attachment, and social organization of the species. Further, differences in the stress regulation system appear to be based on how the neuroendocrine system has adapted to social experiences during early development and may function to prepare developing offspring to deal with the stressors typical of their environment.

### Synonyms

[Eugenics](#); [Lamarckism](#); [Reform Darwinism](#); [Social evolution](#); [Survival of the fittest](#)

### Definition

Set of ideologies loosely based on Charles Darwin's *Theory of Evolution by Natural Selection* that is used to justify certain political, economic, and social policies.

### Introduction

*Social Darwinism* is the co-option of Charles Darwin's *Theory of Evolution by Natural Selection*, to justify certain political and economic practices in human societies. In 1859, Darwin introduced the idea that organisms are in a constant "struggle for survival" in his seminal work *On the Origin of Species*. However, Darwin never posited about the functioning of human societies in his seminal text. Instead, biologist Herbert Spencer drew parallels between his own economic theories and Darwin's biological ones, claiming that the struggle for survival promoted self-improvement in people. In 1864, Spencer published *Principles of Biology*, wherein he promoted the idea that people could genetically pass-on to their children, such learned qualities like frugality and morality (Spencer 1852). Though Spencer is credited as the founder, or "father of social Darwinism," coining the term "survival of the fittest," a phrase commonly used in popular culture to describe any process that is analogous to the biological processes described

by Darwin, the term "Darwinism" was first used by Thomas Henry Huxley in his 1860 review of *On the Origin of Species* (Huxley 1860). Further, the first recorded use of the phrase "social Darwinism" was in Joseph Fisher's article *The History of Landholding in Ireland* published in 1877 (Fisher 1877). Nonetheless, through his adamant re-telling of the theory of evolution, Spencer popularized social Darwinism across the globe, most prominently in Europe and the USA. Unfortunately, the biological theory of evolution and the sociological adaptation of Darwin's theory have never been fully disentangled. As such, social Darwinism has had wide-reaching ramifications, especially as it applies to race, gender, class, and immigration throughout the world.

### History of Social Darwinism

Darwin's biological theory of natural selection and the arguments made later by social Darwinists were heavily influenced by the work of early British cleric and scholar, Thomas Malthus. In his 1758 essay, *Principles of Population*, Malthus argued that resource growth is arithmetic, while population growth is geometric; therefore, populations grow faster than do resources, and this disparity results in a constant struggle among members of a population for scarce resources. While aboard the voyage of the *Beagle*, Darwin read Malthus and began applying these ideas to the natural world, describing a struggle among organisms for access to limited resources in nature. In 1859, Darwin published his ideas about the biological world in arguably one of the most important texts ever written, *On the Origin of Species by Means of Natural Selection*.

The reception of this text was mixed, but one of the first and most vocal proponents of Darwin's theory was biologist Herbert Spencer. Often credited as the founder of social Darwinism, Spencer was also a proponent of *laissez-faire* economics- or the belief that economics and businesses function best when there is no government regulation. At its inception, social Darwinism was largely created as a justification and ethical

precept for cut-throat economic competition. In their view, such unrestrained capitalism was the “natural” order of human civilizations – even though the rise of industrial production at this time was far from “natural.” Many social Darwinists, including Spencer, began opposing laws that helped the poor or working-class peoples, and those that they deemed genetically “unfit.” They argued that such laws would oppose the natural evolution of civilization by delaying the extinction of “unfit” people. However, proponents of social Darwinism have a fundamental misunderstanding about the biological theory proposed by Darwin. Darwin’s theory of evolution by natural selection is the differential survival and reproduction of individuals due to differences in phenotype. Darwin focused on the idea that different phenotypes mean that different individuals will be more or less “fit” to survive and reproduce in a given environment. However, the concept of fitness is biologically open-ended. For example, the phrase “survival of the fittest” is not often used by modern biologists because it is misleading and does not capture the complexity of natural selection as survival is only one aspect of fitness and not always the most important one. Even still, the idea that the existence of “unfit” people in society were inhibiting human evolution, paved the way for new governmental policies that promoted racism, sexism, and xenophobia (Gould 1981).

Social Darwinism has perhaps been the most widely accepted in the USA. While Spencer was well-known across Europe, he was especially popular in the USA because his ideas provided a scientific justification for capitalism, which is believed by many in the USA to be the most effective system for stimulating economic progress. US steel mogul, Andrew Carnegie, was one of the most prominent followers of Spencer and is largely responsible for popularizing social Darwinism in the USA. William Graham Sumner, who held the first Sociology professorship in the USA at Yale University, was a prominent social Darwinist who has had a long-term influence on Conservatism in the USA. Sumner spoke out against the so-called welfare state that promoted a system of government intended to protect the

health and well-being of its citizens – especially, the poor and working class, by means of grants, pensions, and other social programs. Instead, he supported free markets and viewed individual competition for property and social status as a tool for eliminating the weak and immoral people of society (Hofstadter 1944).

## Ramifications of Social Darwinism

The derogatory rhetoric around any person that was not of the dominant, wealthy class, during the height of social Darwinism, paved the way for the new “science” of Eugenics. Invented by British scholar, Sir Francis Galton, Eugenics was marketed as a way to better humankind by propagating the genes of the socially elite (Galton 1883). Just like social Darwinism, Eugenics argued that social institutions like economic welfare, mental health facilities, and disability support programs allowed “inferior” people to survive and reproduce at higher rates than their “superior” counterparts. It is important to note the critical flaws in Eugenic thinking. For one, Eugenics rested on the idea that upper-class people obtained their social positioning because of their superior genetic make-up. It also relied on the idea that “superiority” could be objectively quantified, rather than acknowledging the inherent subjectivity of assessing human qualities.

Eugenics became a popular pseudo-scientific movement in the USA in the early 1900s. Early proponents believed that the best way to improve the human species was to direct its evolution through selective breeding (Davenport 1911). As such, the USA was the first country to concertedly undertake compulsory sterilization programs for the purpose of Eugenics. Rates of forced sterilization were relatively low across the USA, until the Supreme Court’s landmark decision in *Buck v. Bell* 274 US 200, legitimized the forced sterilization of people deemed “intellectually disabled.” After that decision, over 62,000 people in the USA, most of them women and people of color, were sterilized (Kluchin 2011). Forced sterilization disproportionately affected certain

populations including those who were sentenced for harsher crimes and people of color. Wealthy and white-collar criminals were not forcibly sterilized at the same rate. Thus, in 1942, the Supreme Court case, *Skinner v. Oklahoma* 316 US 535, ruled forced sterilization of inmates, unconstitutional under the equal protection clause. Men and women were compulsory sterilized for different reasons. Men were sterilized to treat their “hyper-aggression” and to eliminate “criminal tendencies.” Women were sterilized to control their sexuality. Since women bore children, eugenicists held women more accountable than men for the reproduction of less desirable members of society – another incarnation of sexism propped up by “science.” Many scholars also now recognize that similar Eugenics programs in Nazi Germany were largely inspired by previous work in the USA. In addition to forced sterilization, there were many acts of state-sanctioned racial segregation in the name of Eugenics (Kluchin 2011). These included anti-miscegenation laws that criminalized interracial marriage and sexual relations between members of different races (Dorr 2008).

Eugenics also endorsed strict anti-immigration policies in the USA. The Immigration Restriction League was the first American entity formally associated with Eugenics. Founded in 1894, by three recent Harvard graduates, the League sought to bar what it considered inferior races from entering the USA. Later, Eugenicists like Lothrop Stoddard and Harry Laughlin served as expert witnesses for the House Committee on Immigration and Naturalization. During their testimonies, these men argued that people entering the USA would pollute the national gene pool and dilute what they saw as the superior American racial stock. Some scholars suggest that these racialized arguments prompted the USA and Canada to pass laws creating a hierarchy of nationalities (Kline 2005). Individuals were rated from the most desirable, Anglo-Saxon and Nordic peoples, to the Chinese and Japanese immigrants, who were later banned from entering the country (Gould 1981). This argument that immigrants pollute the USA has never really subsided and is often invoked during every new wave of immigration in the USA.

## Conclusion

Social Darwinism came about during the Industrial Revolution, when many countries were experiencing simultaneous leaps in productivity and massive wealth inequalities. At its inception, social Darwinism was adopted by late nineteenth century capitalists as a justification for *laissez-faire* economics. Under the guise of “science,” the wealthy were considered successful because of their superior genetics, which could be passed to later generations and would positively impact society as a whole. Later, social Darwinism spurred a new movement of Eugenics that propped up racist, sexist, and xenophobic policies – the impacts of which are still being felt across the world. Scholars now recognize social Darwinism as an ideological justification for much of the eighteenth and nineteenth century European enslavement and colonization of countries with valued resources. However, some suggest that these ideas are still working their way into the intellectual foundations of public education in neocolonized countries. We continue to revisit the histories of social Darwinism because many of the ideas are still widely circulated and used to prop-up various social, political, and economic policies across the world today. An evaluation of how social Darwinism has historically affected people can help us avoid the on-going marginalization of people in our societies.

## Social Facilitation

Thomas R. Zentall

University of Kentucky, Lexington, KY, USA

Social facilitation can be defined as the effect of the mere presence of a conspecific (a member of the same species) on the behavior of the focal animal. Robert Zajonc (1965) reported that the effect of the presence of a conspecific may facilitate or retard performance depending on the nature of the behavior being assessed. According to Zajonc, the presence of a conspecific will generally increase the arousal or motivation of the observing organism and that increased arousal would tend to facilitate ongoing (or well learned) behavior but would tend to retard the acquisition of new to-be-learned behavior. Zajonc cited examples from humans (as well as other animals) in diverse settings such as assembly lines and taking exams to running races. This theory has had some support. On the one hand, Zajonc noted that human performance of well-practiced responses on an assembly line were enhanced by the presence of others, as was the performance of well-practiced athletes when competing in the presence of others. On the other hand, when humans performed complex math problems or took difficult tests, the presence of others interfered with performance.

In animals, Zentall and Levine (1972) found that the mere presence of another rat actually retarded the acquisition of a not-yet learned lever-press response for reinforcement relative to the absence of a conspecific, whereas Levine and Zentall (1974) found that if that response had been well learned the mere presence of another rat facilitated the performance of a lever-press response for reinforcement.

One may be able to propose alternatives to social facilitation to account for the reported effects of the presence of conspecifics, however. For example, retarded acquisition of lever pressing can be attributed to the distracting effects of the presence of the conspecific, and the facilitative

effects of the presence of the conspecific on already acquired lever pressing can be attributed to the appearance of competition for a limited resource.

There also appear to be conditions under which the presence of a conspecific can facilitate new learning if that new learning is taking place in a novel, potentially fear-inducing environment. Under such conditions the presence of a conspecific may reduce fear and increase exploratory behavior, leading to faster acquisition of the to-be-learned response (Moore et al. 1981).

Whether Zajonc's theory is correct or not, it is clear that the presence of a conspecific can affect the behavior of the target or focal animal and should be taken into account. This is especially true if one is interested in studying the ability of an animal to learn to perform a response from watching another animal perform the to-be-acquired response. In this case, it is important to include a control condition involving the effect on acquisition of either the mere presence of a conspecific or of a conspecific performing a different response or performing the same response in a different manner (see section on the two action procedure).

A special case of motivation induced by the presence of a conspecific can occur if the animal that is demonstrating the to-be-learned response is motivated by the avoidance of an aversive event (e.g., negative reinforcement). Being in the presence of a conspecific that is avoiding an aversive event can induce fear in the observing animal and that increase in fear can affect the ability of the observing animal to acquire a new response, depending on the nature of the to-be-acquired response but potentially independent of the particular response observed.

Although one would expect members of a social species such as rats and most primates would be more likely to learn from facilitation provided by the presence of a conspecific than more solitary species such as mountain lions, in most mammalian and bird species, the young have extensive interaction with one of their parents, which can exert great influence on their behavior (see, e.g., Lupfer et al. 2003). This would be especially true in reducing fear which would

encourage the young to interact with the environment and encounter reinforcement. The social dynamics that govern the relationships among individuals may be more important than species sociality (Coussi-Korbel and Fragasz 1995). Nevertheless, when it comes to social facilitation, in general, social species will tend to come into contact with reinforcing events more often than less social species (see, e.g., Jackson et al. 2008).

## Social Grooming

Richard McFarland

Department of Anthropology, University of Wisconsin-Madison, Madison, WI, USA

## Synonyms

Allogrooming; Social preening; Social relationships

## Definition

Social grooming behavior is a physical process that functions to maintain the form and composition of another animal's body surface, facilitating improved hygiene and in some cases social bonding.

## Main Text

Allogrooming is the term used to describe when one individual grooms the body of another. Self-grooming is the term used to describe an individual grooming its own body. Both allogrooming and self-grooming serve the primary function of maintaining the form, composition, and cleanliness of an animal's body surface (“► [Grooming](#)”). The function of allogrooming, however, is not limited to the maintenance of the body surface. Animals often engage in allogrooming at rates that far exceed the amount necessary for hygiene alone, and grooming can even occur in the absence of dirt and parasite infestation altogether. As such, allogrooming, or social grooming, also plays an important role in social bonding. Social grooming is seen across a diverse range of animal taxa, including birds, canids, felids, mongooses, primates, rodents, and ungulates. Social grooming is perhaps most conspicuously observed among the primates, with some species spending up to 20% of their active day grooming other group members (Dunbar 1991). Although a great deal of what we know about the functional value of social grooming has come from the primates, similarities have more recently been documented in a range of social mammals and pair-bonded species of bird (e.g., parrots and corvids).

Social grooming and social relationships have become almost synonymous terms in behavioral research, with the quality and patterning of social relationships often being indexed by levels of grooming exchanged between group members (Hinde 1976). It feels good to be groomed. Being on the receiving end of grooming has been associated with endorphin release, lowered heart rates, and reduced social anxiety and baseline stress levels. The role of grooming in social

bonding, especially among the primates, is supported by recent findings linking grooming behavior with the release of neuropeptides including endorphins, “► [oxytocin](#),” and vasopressin (Dunbar 2010).

Many animal taxa live in groups and spend a significant amount of time interacting socially with other group members. The main “benefits of group living” include improved protection from predators, access to food, and mating opportunities, which all contribute positively to an individual's “► [fitness](#).” There are, however, inevitable costs of group living, which typically relate to elevated rates of competition within the group for those same food and mating resources. Competition among group members can lead to aggression and, if left unchecked, can result in the expulsion of the loser from the group and, in some cases, fights to the death. Competition among group members is mediated by the formation and maintenance of social relationships, largely via grooming interactions. Social grooming serves to improve tolerance levels between group members which collectively help maintain group cohesion. Social grooming also plays a direct role in conflict management. Following aggressive conflicts opponents can be seen to exchange grooming in an apparent attempt to reconcile their differences (“► [Post-conflict Resolution](#)”). Conciliatory grooming has been shown to reduce social tension and repair the opponents' damaged social relationship, helping to moderate the potential long-term negative consequences of a conflict.

Individuals more integrated in to their group, via social relationships, experience improved health, longevity, and offspring survival, compared to those more socially isolated. Although social relationships have been tied to fitness benefits in a range of animal taxa, the underlying mechanisms for this relationship are less understood (Ostner and Schülke 2018). It has been argued that more sociable individuals experience less physiological and psychological stress than those less sociable. Social relationships can also provide direct energetic benefits. More sociable individuals may get better access to nutritional resources due to the increased tolerance afforded by other group members when feeding (de Waal

1997). More sociable animals also get better access to huddling partners in cold conditions (McFarland et al. 2015). The improved energy resources available to more social individuals facilitate longevity, a greater energetic investment in reproduction, and offspring survival. Elucidating the physiological mechanisms that mediate the relationship between sociability and individual fitness remains an important focus of research on social relationships and social grooming.

Grooming is an inherently valuable resource, and individuals groom one another with the expectation of receiving grooming, or another social commodity, in return. Grooming as a social commodity is based on the viewpoint that animal groups serve as biological markets in which animals trade behavioral interactions (Noë and Hammerstein 1995). Social grooming is exchanged between group members to receive, for example, reciprocal grooming, spatial tolerance, reduced aggression, agonistic support, access to mating opportunities, food sharing, and infant handling. Displays of grooming during courtship are observed in many mammals and birds, and even some arthropods, where the groomer has a better chance of mating following the provision of grooming. The framework of a biological market explains how, and to what extent, social commodities are exchanged within a given group. The biological market approach posits that individuals differ in the types of commodity they exchange with one another, that different commodities hold different values, and that the value of a commodity is dependent on the value the recipient attributes to the donor. That is, no two individuals are likely to value each other to the same degree, which means grooming exchanges are unlikely to be symmetrical. Grooming is preferentially directed toward close kin. The maternal grooming of offspring is particularly widespread in animals. Dominant individuals are generally considered to be more attractive social partners and tend to receive more grooming than subordinate group members. Dominant individuals can trade their tolerance for the benefits of grooming and have even been observed to coerce

or punish the behavior of subordinates to gain preferential access to grooming.

It is currently debated whether animals have the cognitive capacity to keep track of grooming exchanges and its “► [reciprocity](#)” over time. Grooming reciprocity is based on a tit-for-tat scenario where two individuals switch social roles (i.e., donor or recipient), so that the costs and benefits of these acts are balanced over time. In a tit-for-tat scenario, short-term reciprocal exchanges should be favored as a way to avoid cheating. Grooming reciprocity, however, may not solely be based on the expectation of an immediate reward but may also reflect a calculated exchange based on a shared history of previous social interactions (de Waal and Luttrell 1988). Calculated reciprocity could explain patterns of long-term grooming reciprocity, although this would require advanced cognitive skills such as memory, numerical assessment, and planning. Calculated reciprocity is therefore thought to be restricted to humans and possibly the great apes. Alternatively, long-term reciprocity could be sustained via emotional bookkeeping (Schino and Aureli 2009), whereby grooming elicits positive emotions that modulate an individual's choice of social partners for future social interaction. This emotion-mediated mechanism is not thought to require complex cognitive skills.

## Social Intelligence Hypothesis

Alizée Vernouillet

University of Manitoba, Winnipeg, MB, Canada

### Definition

The Social Intelligence Hypothesis stipulates that increased complexity in social groups has resulted in larger brains and more advanced cognitive abilities in primates. The Social Intelligence Hypothesis was developed as an answer to why primates, especially humans, possess highly advanced cognitive skills in comparison to other animal species. This enhanced “intelligence” is often associated with the development of certain brain areas associated with complex cognitive abilities (e.g., neocortex) and overall with a larger brain than would be expected given the species’ body size.

### History

During the 1950s and 1960s, researchers started to suggest that large brains in primates were due to their complex social life. The ideas that would later lead into the full concept of the Social Intelligence Hypothesis were first proposed by Michael Chance and Allan Mead in 1953 (Chance and Mead 1953), as they linked social complexity and enlargement of the neocortex in primates, and were later developed by Allison Jolly in 1966 (Jolly 1966), when she compared long-term social groups of lemurs and primates. The Social Intelligence Hypothesis was then fully described by Nicholas Humphrey in 1976 (Humphrey 1976) under the name of “social function of intellect.” Humphrey proposed that primates possessed a social intelligence that was responsible for their general advanced cognitive abilities.

Hence, the Social Intelligence Hypothesis was mainly developed to explain why primates, and more especially apes, possess a larger brain than

expected by their body size, as well as a more advanced “intelligence” or more complex cognitive abilities than other species (Jerison 1973). Among them, humans are known for having a very complex social system that involves cooperation within and between generations by dividing the labor to facilitate daily tasks (Richerson and Boyd 1998) and, at the same time, possessing the largest brain relative to their body size in comparison to other animal species. At the time, researchers deemed that ecological pressures such as foraging and evading predators were not sufficient to explain the complex cognitive abilities in primates, as other species experienced similar pressures but were argued to not possess such advanced cognitive skills. Furthermore, since brain tissues are costly to produce (Aiello and Wheeler 1995), a bigger brain than expected by body size must be evolutionary advantageous for a species to possess. In addition, bigger brains were often associated with distinctive complex cognitive abilities (Rothe and Dicke 2005), such as tool use and manufacture.

Early studies focusing on the relationship between cognitive abilities and social complexity in animal species were primarily conducted on primates, due to their close relatedness to humans. Among primates, a preference was made for Old World monkeys and apes because their ecology and behaviors were better known than those of New World monkeys (Perry 2009). Today, the Social Intelligence Hypothesis is being tested in a wide array of animals, including birds, cetaceans, and elephants. Expanding the research to other species has led to a refinement in the Social Intelligence Hypothesis and to the development of derived hypotheses.

## Mechanisms

As an individual living in a social group is surrounded by other individuals, many of its actions will influence the rest of the group. Therefore, an individual needs to take into account other group members by predicting how each group member will react when it performs the action. That ability involves being able to track

individuals within their social group, remembering the past interactions, whether cooperative, neutral, or competitive, with the other members, but also keeping track of changes in the hierarchy and the roles of each individual over time. Since interactions within a social group are complex, it is difficult to predict the actions of other members in the group. However, as individuals get accustomed to each other, they come to know how each individual tends to behave when interacting with others or in a given situation. In addition, as individuals cooperate with each other, some expectations (e.g., reciprocity, advantage for accessing some resources) need to be met in order for that relationship to survive between them. This complexity is enhanced by the fact that individuals cannot be treated and manipulated like physical objects, but their behavior can be controlled using direct or indirect communication. As a result, the bigger the group size, the more cognitively demanding it is for an individual to process and integrate all the social information occurring within the group and require more advanced social cognitive skills to cope with such high social demands (Byrne and Whiten 1988).

Living in a group also has its advantages (Rubenstein 1978). From an ecological point of view, group living allows individuals to reduce the risk of predation on themselves by diffusing that risk among other members of the group. From a social point of view, it leads to social learning, which allows an individual to learn the consequences of an action by observing other individuals performing that action. Social learning can then lead to teaching and, potentially, transmission of behaviors across generations (i.e., culture). In addition, having other individuals in a group cooperating when faced with a novel problem allows individuals to be exposed to alternative solutions from others and thus permits individuals to more readily cope with novel situations. More efficient mechanisms to forage and to survive are then selected, leading toward an increased general intelligence within the group.

By successfully recording the social information of the group and using “politics” to gain access to resources, an individual can rise higher in the hierarchy of the group. In most cases, a more dominant

position within the group implies a higher chance to transmit genes to the next generation.

## Support for the Social Intelligence Hypothesis

To test the Social Intelligence Hypothesis, most studies undertake a comparative approach. Comparing brain structures or cognitive abilities between closely related species that differ mostly in their inherent social complexity can help detect whether sociality is the main factor underlying the evolution of brain size or specific cognitive abilities (e.g., MacLean et al. 2012).

Early support for the Social Intelligence Hypothesis came from the comparison between the relative size of the neocortex (i.e., brain area involved in higher cognitive functions), in comparison to the species' body size, and the average group size within primates (Dunbar 1992). A positive correlation exists between those two factors, indicating that larger brains might be needed to cope with larger social groups. Differences also occur between apes and monkeys, as apes possess a larger brain than monkeys living in a group of the same size. This difference in brain size suggests that apes have a more complex social structure than monkeys (Dunbar 2014). More recently, a neuroanatomical approach has been used to test the Social Intelligence Hypothesis, and most studies comparing the neuroanatomy across primates have supported the Social Intelligence Hypothesis. However, results of these studies are to be interpreted with caution as most of them used the average group size in a species as a proxy for social complexity (Dunbar and Shultz 2007). This aspect might bias the results as some species can form large groups, but any individual might not interact with all members of the group. Additionally, smaller groups can engage in much more complex interactions with the other members than found in larger groups. For this reason, recent versions of the Social Intelligence Hypothesis focus not solely on the quantity of the relationships between individuals but also on the quality of those relationships (Dunbar 2014). This twist in the Social

Intelligence Hypothesis has been used to explain the complex cognitive abilities found in birds (e.g., corvids, parrots), wherein some monogamous species with very strong pair bonds can possess cognitive skills on par with those of great apes (Emery et al. 2007).

In humans, specifically, archaeological evidence has shown that brain size dramatically increased twice in history. These two periods of human brain expansion have been linked to increased group size in humans (Mithen 1996). The first brain size increase occurred ca. 1.8 million years ago: brain size in early humans increased from 450 cc (cubic centimeters) to 1000 cc. This increase has been linked to a change in the social life in hominins (early humans), as individuals started to live in more complex and larger groups. The second brain size expansion dates between 600,000 and 200,000 years ago, leading the brain to increase to its current capacity (around 1450 cc). This growth has been linked to the evolution of language, an important element for the mediation of social relationships.

## Critiques of the Social Intelligence Hypothesis

The Social Intelligence Hypothesis is often put in contradiction with the Foraging Niche Hypothesis (Gibson 1986; Milton 1988). The Foraging Niche Hypothesis explains the presence of bigger brains in primates by arguing that bigger brains have evolved so that individuals can cope with the complexity of their environment when foraging on complex substrates or in unpredictable environments. While both hypotheses acknowledge the fact that ecology is the main cause for brain evolution, they differ on the most important selective pressures. The Social Intelligence Hypothesis argues that animals solve ecological problems (foraging, protection from predators) by using a social approach, thus maximizing their access to resources. It also deems that the social environment is more challenging and less predictable than the ecological environment (Dunbar 1992), whereas the Foraging Niche Hypothesis suggests that finding food and avoiding predation are more

direct evolutionary pressures. Indeed, primate species with larger brains tend to have a larger home range and feed primarily on fruits, an ephemeral, widely dispersed resource (Milton 1988).

Even within the scope of the Social Intelligence Hypothesis, earlier forms of the hypothesis were criticized as being very primate-centric. Primates have an enlarged neocortex in comparison to other mammals (Jerison 1973), and that was thought to be the reason for why they possess such advanced cognitive abilities. However, recent studies have shown that corvids (e.g., crows, jays) and parrots, which lack a neocortex, possess cognitive abilities that are on par with those possessed by apes (e.g., Emery and Clayton 2004). Further studies suggest that neuron densities might be a more effective approach of judging a species' brain size and a more relevant factor explaining advanced cognitive abilities than sociability (Olkowicz et al. 2016). Thus, using more distantly related species displaying similar cognitive abilities allows testing the validity of the Social Intelligence Hypothesis.

## Derived Hypotheses

Since it was formulated, a few other hypotheses have emerged to complement or to clarify the Social Intelligence Hypothesis. Examples of such hypotheses include the Machiavellian Intelligence Hypothesis, proposed by Andrew Byrne and Richard Whiten in 1988 (Byrne and Whiten 1988), and the Social Brain Hypothesis, suggested by Lesley Brothers in 1990 (Brothers 1990) and popularized by Robin Dunbar in 1998 (Dunbar 1998).

Byrne and Whiten described the Machiavellian Intelligence Hypothesis following observations of "tactical deceptions" in wild baboons (Byrne and Whiten 1988; Whiten and Byrne 1997). The Machiavellian Intelligence Hypothesis puts the emphasis on social maneuvering (e.g., collaboration, rivalry, alliance formation) as the most important factors underlying the evolution of a larger brain and, consequently, advanced cognitive skills. According to the authors, the ability to

manipulate and form alliances with others in order to gain access to resources was the prime reason that led to the evolution of advanced cognitive abilities in primates. Indeed, tactical deception is thought to be the main social pressure increasing the fitness (reproduction output and survival) of the deceiver. It thus slightly differs from the Social Intelligence Hypothesis by emphasizing on the importance of tracking the alliances and coalitions between the members of the group.

The Social Brain Hypothesis primarily focuses on the correlation between the mean social group size and brain size (or certain brain structures in primates). According to this hypothesis, the need to keep track of the complex relationships between individuals explains the existing correlation between relative brain size of a species and the average size of its social group (Dunbar 1998). Hence, it is a more subsidiary generalization than the overall Social Intelligence Hypothesis.

## Importance and Impact of the Social Intelligence Hypothesis

Since its formulation more than half a century ago, the Social Intelligence Hypothesis has led to new avenues of research. Not only did it permit the exploration of social cognitive abilities in social species, it also encouraged the search for complex cognitive abilities in nonsocial species, or in species that were previously disregarded as "unintelligent" (e.g., birds, invertebrates), in an attempt to refute the Social Intelligence Hypothesis. This approach has led to adjustments in the formulation of the Social Intelligence Hypothesis to encompass recent research on less social species, by focusing on the quality of the social relationships between the members of a group and not just the number of individuals within a social group (Dunbar and Shultz 2007).

The Social Intelligence Hypothesis also paved the way for research on Theory of Mind (i.e., the ability for an individual to attribute mental states such as beliefs, desires, emotions to others) in nonhuman animals. Indeed, the Social Intelligence Hypothesis is relying on the ability of individuals to identify other group members, to

recognize them, and to “read their minds” (Premack and Woodruff 1978). By examining whether a given species possesses elements of a Theory of Mind, researchers have been able to understand more about the components present in a social group and determine which elements underlie complex social cognition. However, the issue of whether (and which) animals possess aspects of a Theory of Mind is still highly debated.

Even currently, the Social Intelligence Hypothesis is highly relevant in the field of cognition and continues to be one of the main explanations for the evolution of complex cognitive abilities in animals. It is now commonly accepted that sociality played a part in the evolution of “intelligence,” but its relative role remains to be determined. Ultimately, the Social Intelligence Hypothesis has not only allowed us to discover interesting and complex cognitive abilities in other nonhuman animal species, it has also made us wonder which cognitive skills are inherently unique to humans and what made us different from other animal species.

## Social Learning

Sonja Wild and William J. E. Hoppitt  
School of Biology, University of Leeds,  
Leeds, UK

### Definition

“Social learning is learning that is facilitated by observation of, or interaction with, another individual (or its products)” (Hoppitt and Laland 2013) modified from (Heyes 1994). This widely used definition serves well to classify the types of learning that are covered by research into social learning. However, the definition is very broad meaning that researchers use additional, narrower definitions to identify more specific types of social learning. Of particular interest is social learning that results in one individual (termed the “observer”) learning a novel behavior pattern after having been exposed to another individual (termed the “demonstrator”) performing that behavior. Such learning is sometimes called “social transmission,” which can be defined as occurring “when the prior acquisition of a behavioral trait  $T$  by one individual  $A$ , when expressed either directly in the performance of  $T$  or in some

other behavior associated with  $T$ , exerts a lasting positive causal influence on the rate at which another individual  $B$  acquires and/or performs  $T$ ” (Hoppitt and Laland 2013). The term “cultural transmission” is used in a more specific way to refer to cases of social transmission that increase behavioral homogeneity within groups of individuals (i.e., can result in the emergence of culture).

## The Spread of Innovations

Social learning describes the process of sharing information between two individuals. The individual who holds the information is often referred to as the “demonstrator,” whereas the individual that learns socially is referred to as the “observer.” Information shared between demonstrator and observer can include novel behaviors or knowledge that the demonstrator has acquired. Before information can spread through a population, it has to be generated through an “innovation.” Such an innovation can include the discovery of novel information, the establishment of a new behavior, or the performance of an already established behavior in a different context (Reader and Laland 2001). Innovations are products of “asocial” or “independent” learning, which requires sampling of the environment by the demonstrator followed by finding an appropriate response, often through trial and error learning. Hence, asocial learning generates innovations, while social learning is responsible for the spread of such innovations.

## Learning at Different Life Stages

Social learning can occur at many different stages in life, even before birth. Individuals can show preferences for food that they were exposed to through food cues in the womb through their mothers’ amniotic fluid (e.g., Smotherman 1982). Similarly, flavor cues in the mother’s milk that individuals were exposed to early in life can influence food preferences as adults. Particularly young individuals during dependency rely heavily on learning from others. At this life stage, skills crucial for survival have to be learned

rapidly, including knowledge about foraging techniques, diet, predator avoidance, interaction with conspecifics, or seeking shelter. Social learning from older, more experienced conspecifics can thereby greatly increase the efficiency with which all these skills are acquired as well as decrease the risks associated with independent learning. The rate at which individuals learn from others might decrease with age, but social learning continues into adulthood. Even for adults it can be beneficial to use information that has been gathered by others such as location of food patches or copying behaviors that have been innovated by someone else. In a group of wild chimpanzees, for example, moss-sponging – an innovative technique to retrieve water from a water hole – was found to be socially transmitted within the group, including among adult individuals (Hobaiter et al. 2014).

### Social Learning Mechanisms

Over the years, a number of researchers have attempted to classify social learning mechanisms into categories. However, there is no universally accepted classification. Nonetheless, there are a number of terms that are used in a consistent manner to refer to particular types of social learning. Some of these mechanisms result directly in learning on the part of the observer, whereas others influence the behavior of the observer in way that indirectly leads to learning. An example of a mechanism that indirectly leads to social learning is **local enhancement**, which occurs when, after or during a demonstrator's presence or interaction with an object at a particular location, an observer is more likely to visit or interact with the object at that location (Hoppitt and Laland 2013). Local enhancement can lead indirectly to social transmission, if the performance of a behavior pattern leads observers to a location at which that behavior pattern can be learned. The technique for processing a particular plant might be socially transmitted, if local enhancement leads observers to locations at which those plants occur, leading them to learn (in an otherwise asocial manner) how to process those plants. An example of a mechanism that directly leads to social

learning is **observational conditioning**. Here the demonstrator exposes the observer to a relationship between two stimuli, allowing the latter to form an association between those stimuli (Heyes 1994). Such social learning allows an observer to learn about its environment through observation. Other mechanisms, such as **imitation** and **emulation**, allow an observer to learn to perform novel behavior that is not already in its behavioral repertoire.

Social learning need not always require the observer to literally observe the demonstrator's behavior. Instead, social learning might occur when the observer is exposed to the products of the demonstrator's behavior. For example, Heyes and Dawson (1990) found that observer rats would socially learn to press a joystick in a particular direction for a food reward and that this behavior could be transmitted via olfactory cues left on the joystick.

Most nonhuman animal social learning appears to result when a demonstrator “inadvertently” provides the cues to allow the demonstrator to learn. However, evidence is accumulating that a number of species are capable of “**teaching**” in the functional sense (Caro and Hauser 1992), i.e., that they perform behavior which has the evolutionary function of promoting learning in others. In such cases, it seems plausible that teaching has evolved to take advantage of pre-existing social learning mechanisms that exist in the observer (Hoppitt et al. 2008).

### When Is Social Learning Adaptive?

Social learning can greatly increase an individual's fitness. By learning from others, individuals can save on the costs associated with trial and error learning, as they do not have to acquire the information themselves. Costs involved in individual learning can be manifold. For example, trial and error learning can be very time-consuming if the acquisition the novel information requires extensive sampling of the environment or if many attempts are required to find a solution to a challenge. Costs associated with independent learning can also be very severe, if

errors during the learning process result in an increased risk of mortality, such as in the context of predator avoidance or ingestion of potentially poisonous food. Therefore, it is not surprising that individuals tend to rely more extensively on information gathered by others, if the costs associated with individual learning are potentially high. Social learning is hence commonly, but not exclusively, found in a foraging context, as well as predator avoidance, but also in other, lower-risk contexts such as hygiene or play. Examples for social learning in nonhuman animals are numerous. Most evidence of social learning comes from a foraging context, where information on what, where, and how to eat is shared among individuals. Immature Bornean orangutans, for example, were found to adopt their mothers' diet through social learning by consistently following their mothers' choice of what and how to eat (Jaeggi et al. 2010).

Intuitively, one would expect all individuals to rely on information gathered by others to save the costs associated with independent learning. However, this view is too simplistic: While independent learning *produces* information or novel behaviors, social learners *scrounge* on information that has been acquired without contributing to new information themselves. Game theory models of producer-scrounger interactions suggest that relying on information gathered by others does not necessarily increase benefits, as scroungers only do better than producers, if fellow scroungers are rare (Barnard and Sibly 1981). Asocial learners have acquired information about the environment at some cost. As the number of social learners increases, the number of asocial learners who produce reliable information declines. Assuming a changing environment, a decrease in the proportion of information producers would thus result in a decline of the value of socially acquired information. Hence, for social learning to be adaptive, a population is expected to reach an equilibrium at which social learning and independent learning have equal fitness benefits (Boyd and Richerson 1988). If information gathered by the demonstrator lacks appropriate sampling of the environment and is thus unreliable, copying such information is no longer

beneficial to the observer or can in fact be costly. If the latter, social learning is maladaptive, and the proportion of social learners is expected to decrease, while the proportion of independent learners is expected to increase to again produce more reliable information.

Similar reasoning leads us to expect social learning to evolve only when the environment does not change too quickly or too slowly (Laland et al. 1996). If the environment changes too quickly, information obtained second, third, or fourth hand, etc. is likely to be outdated by the time the observer receives the information. In such cases, it is adaptive to rely on asocial learning and obtain up-to-date firsthand information about the environment. If the environment changes very slowly, then one would not expect learning to be necessary at all, with individuals relying on "hard-wired" behavior and natural selection keeping track of environmental change. Thus, social learning is likely to be favored in case of intermediate environmental change.

Taken together, this theory suggests that the use of social learning should be selective, with individuals employing "social learning strategies" determining when to copy other individuals (Laland 2004). Furthermore, one would expect social learning strategies that determine *who* observers should copy to obtain the best quality information and also *what* types of information should be copied (Laland 2004).

## Social Learning in Animal Species

Evidence for social learning has been found in a variety of different animal taxa including primates (e.g., Hobaiter et al. 2014; Jaeggi et al. 2010), cetaceans (e.g., Allen et al. 2013), birds (e.g., Farine et al. 2015), fish (e.g., Helfman and Schultz 1984), and insects (e.g., Alem et al. 2016). A species' social system and several life history traits can be linked to the frequency of social learning and complexity of the information that is shared among individuals.

Long-lived species that live in stable social societies tend to rely heavily on the social transmission of information, whereas in short-lived

and more solitary species, learning from others is rather uncommon. In long-lived species with intensive and prolonged parental care, especially young naïve individuals rely extensively on social learning to acquire all necessary skills to ensure survival after weaning. In primates and birds, both rates of innovation as well as the frequency of social learning were found to be positively correlated with relative brain size (Lefebvre et al. 2004; Reader and Laland 2002). Hence, species with advanced cognitive abilities appear to be able to both generate as well as spread novel information at a higher rate compared to species with smaller relative brain sizes.

The complexity of information shared between demonstrator and observer can vary greatly from very simple information to a complex series of behaviors. Complex behaviors that are likely to be socially transmitted, such as using tools for extractive foraging tasks, are mainly found in species with advanced cognitive abilities such as great apes, toothed whales, and large-brained birds such as corvids. In smaller brained species, sharing simple information, such as the location of food patches, is more common.

Apart from the kind of the information that is shared among individuals, the complexity of the social learning mechanisms also varies greatly within the animal kingdom. Whereas simple mechanisms such as local or stimulus enhancement and/or observational conditioning are likely to be present in many species, more complex mechanisms such as imitation seem restricted to species with higher cognitive abilities.

Although learning from others most commonly happens within a species, sharing information among species can occur. For example, information on the location of novel foraging patches was observed to spread both among and within species in a population of blue tits, great tits, and marsh tits (Farine et al. 2015).

## Social Learning Experiments

Laboratory studies (i.e., studies on animals in a captive setting) have shown the existence of

a capacity for social learning in many animal species. The classic way to investigate if a species is capable of social learning in a captive environment is to use a **demonstrator-observer experiment** (Hoppitt and Laland 2013). In the training phase, one individual (the demonstrator) is trained to be proficient at solving a particular task (e.g., pressing a lever for a food reward). In the demonstration phase, another individual (the observer) either directly observes the demonstrator solving the task or is exposed to the physical products of the demonstrator's actions. In the test phase, observers are presented with the task and given an opportunity to solve it. If observers are more likely to learn the behavior, or do faster than control animals who do not see a demonstration, then one has evidence that social learning has occurred. In the classic setup of the demonstrator-observer experiment, one observer learns socially by observing one trained demonstrator. However, many variations of the experiment are possible, such as increasing the number of demonstrators and investigating how this number influences the rate at which observers learn the target behavior. The experiment can also be modified to distinguish between different mechanisms of social learning, such as distinguishing imitation from other mechanisms of social learning. Akins and Zentall (1996), for example, provide evidence for imitation in male Japanese quails in a so-called two-action experiment, where quails witnessed a demonstrator quail receive a food reward when pressing a treadle, either by pecking it or stepping on it. After the demonstrator had been removed and the observer was presented with the experimental setup, the subject's first action was always the same as the demonstrator's.

An alternative to the classic dyadic demonstrator-observer experiment are **transmission chain studies**, in which the first observer acts as a demonstrator to another individual after acquiring the behavior via social learning from the initial demonstrator. In the **linear transmission chain experiment**, information or a behavior is transmitted along a single line of subjects. Linear transmission chain studies are not only useful tools to "prove" the capacity for social learning in

a population, but they also allow to investigate the factors influencing the rate of social transmission and assess the potential loss of information. Bartlett (1932), for instance, who originally developed the linear transmission chain experiment, presented a text or picture to a first participant, who later recalled it to the next participant in the line, who again recalled it to the third participant, and so on, and changes to the originally presented material were assessed as the line continued. It turned out that it was largely cultural biases that influenced the rate of degradation of the material, as well as how the material was changed along the line of participants.

Linear transmission chains in a laboratory setup allow to track the diffusion of the behavior in a stepwise manner to determine at which point the behavior differs from the one introduced to the original demonstrator. One can then assess the factors that influence the process of social transmission and identify those that determine whether knowledge or behavior is lost, gained, or altered along the transmission chain. The alternative to linear transmission chains are **replacement transmission experiments** (Gerard et al. 1956), in which a behavior is introduced to a small group whose members are gradually replaced over time. At each step, an experienced member is replaced by a naïve subject until at some point there is no more contact with the original members of the group. Evidence for social transmission is found, if the introduced behavior persists in the population even though the trained demonstrators of the original group have been replaced. In a replacement transmission experiment in rats, for example, four demonstrator rats in two populations each were conditioned to prefer one of two flavored diets, with individuals in the same population having the same preference (Galef and Allen 1995). Individuals in both populations were gradually replaced with naïve individuals, who consistently chose to follow the dietary preference that had initially been introduced to the respective population, leading to a stable transmission of two completely arbitrary dietary preferences (Galef and Allen 1995).

A third way to assess social learning patterns in a population in a laboratory setting is **diffusion**

**studies**. Here, a task (usually a foraging task) is introduced into several replicate populations, and the spread of task solutions is recorded. In “seeded diffusions,” trained demonstrators may be introduced into the population, sometimes even several demonstrators with alternative solutions to a task. Populations without demonstrators can serve as control. Thornton and Malapert (2009), for example, trained individual demonstrators in several groups of wild meerkats to obtain food from an apparatus using one of two techniques, while groups with no demonstrators served as controls. In the experimental groups, several individuals adopted the demonstrator’s technique after interacting with either the demonstrator itself or group members that had already learned the behavior from the demonstrator. As opposed to the classic demonstrator-observer experiment and the transmission chain studies, diffusion studies do not impose an artificial structure on the social interactions between individuals, but the novel behavior can spread in a more naturalistic manner within the population.

A fourth way of studying social learning in an experimental setting is **translocation studies**. These studies can be used to test whether behavioral variation among populations is a result of different innovations being socially transmitted among individuals in each population. In one translocation, individuals are transferred to a different population they have never been in contact with. If over time, the transferred individuals adopt the residents’ behavioral repertoire, this is consistent with social transmission and inconsistent with behavioral differences being a result of different genetic predispositions. Additionally, entire populations can be replaced instead of single individuals. If the introduced population exhibit a behavior that is different from the former residents, this is consistent with the behavior being cultural, i.e., having been socially transmitted within the population. In contrast, if the new group adopts the same behavior as the former residents, it instead suggests that behavioral variation was a result of individuals independently learning to adapt to the local environment. Translocation experiments are not restricted to laboratory settings. Helfman and Schultz (1984), for

example, applied a translocation experiment to a population of free-living French grunts, a coral reef fish species, who have local traditions of schooling sites during the day and specific twilight migration routes. They found that individuals that were translocated to new schooling sites adopted the customs of the new residents and abandoned their old schooling sites and migration routes, which suggest the existence of socially learned local traditions. However, translocation experiments may sometimes be unfeasible or unethical to be applied to free-living animal populations, such as great apes, for example. Instead, natural movements of individuals or populations can be exploited as translocation experiments, although under less controlled conditions compared to laboratory settings.

Finally, **cross-fostering experiments** can shed light on whether “vertical” social learning (from one’s parents) can occur in a species. Thereby, offspring are taken from their biological parents at birth and given to foster parents to be raised. These experiments are useful to investigate the extent to which “vertical” social transmission from the parents influences an individual’s behavior, relative to genetic influences. Any behavior readily adopted from the foster parents, when it differs from the behavior exhibited by the biological parents, is likely to be vertically socially transmitted under natural circumstances. This inference may assume that the environmental conditions under which both biological and foster parents live are equal.

Laboratory settings have the advantage of replicability as well as control over a range of potentially confounding factor such as the influence of environmental variables. The history of individuals subjected to experiments is generally known, and it can be ensured that the task they are presented is indeed novel. Furthermore, experiments are permanently monitored, and social learning events can be recorded without gaps. The ability to gather data in such a highly controlled environment thus provides invaluable opportunity to study the existence of a capacity for social learning and the underlying mechanisms within animal populations. However, experimental setups in a laboratory environment are often quite different

from wild populations and lack ecological validity and thus may not be able to tell us how important social learning is in natural settings.

## Detecting and Measuring Social Learning Using Observational Data

In some circumstances, it may be desirable to test whether social learning is occurring in the field, in a natural population of animals. It may not be possible to study the target species in a captive setting, meaning field studies are the only way to establish whether that species has a capacity for social learning. And even if captive experiments have been performed on that species, researchers may still wish to quantify the importance of social learning on the diffusion of naturally occurring innovations in the field. In some circumstances, it may be possible to run field experiments, for instance, seeded diffusion studies conducted on natural populations (see entry on Cultural Transmission). However, this is not always possible necessitating techniques for inferring social learning from observational field data.

One method traditionally used to do this was **diffusion curve analysis (DCA)**. A diffusion curve plots the number of individuals having been observed performing the behavior pattern of interest against time. For many years, it was believed that the shape of the curve could be used to infer whether social learning is responsible for the spread of a novel behavior. It was assumed that if a behavior is purely independently learned, the curve would result to be r-shaped, as the per capita rate of learning is expected to be approximately constant, with the curve leveling off as the whole population has learned the behavior (Fig. 1a). In contrast, if the novel behavior spreads through social learning, it is expected to result in an acceleratory curve, as the rate of learning would increase with the number of demonstrators over time. If the entire population acquires the novel behavior, the curve is expected to be s-shaped, as when either demonstrators or observers are rare – which is the case at the start and end of a diffusion – the learning rate would be lower compared to when demonstrators and

**Social Learning, Fig. 1** Diffusion curves are traditionally expected to be (a) **r-shaped** in case of **asocial** and (b) **s-shaped** in case of **social transmission** of behavior.

However, theoretical work has shown that diffusion curve analysis (DCA) is not a reliable approach to distinguish between asocial and social learning

observers exist in equal numbers (Fig. 1b). Although frequently used in the past, recent analyses have shown that diffusion curve analysis is not a reliable signature to identify if a behavior is socially learned or not. There are various reasons for that: First of all, if a behavior is socially learned, the shape of the curve does not necessarily have to be s-shaped. If the population consists of several social subgroups, the curve could be step-shaped with accelerations in rate when a behavior diffuses rapidly within a social subgroup and slower rates for diffusion between subgroups (Reader 2004). Also, differences in the rate of social learning between subsections of the population (e.g., male/female, high/low-rank) might obscure results (Reader 2004). Furthermore, even a purely asocially learned behavior can result in an s-shaped curve, if, for example, neophobia right after initiation of a novel task can lead to reduced rates of learning, followed by increased rate of learning after neophobia has worn off (Hoppitt et al. 2010b). In conclusion, diffusion curve analysis cannot be used to reliably identify social or asocial learning as being the driving mechanism behind the diffusion of a novel behavior.

Among primatologists, a commonly used method for the detection of social learning was

the **method of exclusion** (sometimes known as the **ethnographic method**) (e.g., Boesch 1996; van Schaik et al. 2003; Whiten et al. 1999). This method compares behavioral repertoires of different populations and identifies group-typical behavior that varies among groups. A number of hypotheses can then be proposed for why such group-typical behavior has emerged. The *cultural hypothesis* states that different innovations have arisen in each group and spread by social transmission. The *genetic hypothesis* states that different groups are genetically predisposed to behave in different ways. Finally, the *ecological hypothesis* states that in learning to adapt to their local ecology individuals within a group converge on similar repertoires that differ from the repertoires of individuals in other groups. The method of exclusion attempts to rule out the genetic and ecological hypotheses as sufficient explanations for the observed pattern of variation, thus showing that social learning is likely to have played a role.

Critics of the method of exclusion (Laland and Janik 2006) claim that it fails to estimate the relative importance of social learning/culture in nature, arguing that it only identifies cases where genetics and ecology can be ruled out, whereas it is likely that these factors play a role in most

cultural behavior. Proponents of the technique (Krützen et al. 2007) have countered that the purpose of the method of exclusion is not to assess the relative importance of culture in behavioral variation between populations but to detect culture (i.e., a role for social learning in generating behavioral variation) in natural populations. Nonetheless, it is generally agreed that behavioral differences can simultaneously be a result of genetic, ecological, and cultural influences and that a quantitative estimate of their influence on behavioral variation is desirable (Krützen et al. 2007; Laland and Janik 2007).

As an attempt to resolve this “animal culture debate,” a method called **network-based diffusion analysis (NBDA)** has been developed (Franz and Nunn 2009; Hoppitt et al. 2010a) in order to provide a framework by which social learning among members of a group or population can be quantified. NBDA assumes that social transmission of a behavior follows the social network of associations or interactions among individuals, since individuals who spend a lot of time together or who interact more have more opportunity to learn from each other (Coussi-Korbel and Fragaszy 1995).

Therefore, NBDA infers social transmission if the spread of a novel behavior follows the social network of a population (Fig. 2). NBDA thus

allows the study of social learning to be linked to animal behavior research that uses social network analysis. NBDA fits a model of social learning to the diffusion data, i.e., data giving the order or times at which each individual in the population learned the novel behavior. The fit of this model is then tested against a null model in which there is no social learning: the pathway of diffusion is independent of the network. NBDA does not only serve as a tool for the detection of social learning but also allows the estimation of the strength of the social transmission effect. A social transmission parameter,  $s$ , is fitted to the data and estimates the rate of transmission per unit association with informed individuals relative to the average rate of asocial learning (Hoppitt et al. 2010a).

In addition, several individual-level variables can be included in the analysis, which have potential influence on an individual’s learning rate (e.g., gender, rank, or age), and can also be used to model the effect of and statistically control for potential ecological and genetic influences. NBDA has been successfully used in a number of studies to identify and quantify the effects of social transmission on the spread of behaviors in both wild and captive animal populations such as starlings (Hoppitt et al. 2010a), chimpanzees (Hobaiter et al. 2014), or humpback whales (Allen et al. 2013).

**Social Learning, Fig. 2** Network-based diffusion analysis (NBDA) tracks the spread of a behavior through the social network of a population. Numbers represent the order with which individuals acquire a novel behavior.

NBDA infers (a) **social transmission** if the diffusion follows the network and (b) **asocial learning** if the spread of the behavior happens independently of the network

## Conclusions

Social learning is a broad category of phenomena that includes “social transmission” and “cultural transmission,” which result in the diffusion (spread) of matching behavior among individual animals in a group. Some social learning researchers are interested in the psychological mechanisms underlying social leaning (e.g., imitation). Others are interested in the circumstances under which social learning is adaptive and the strategies animals use in deciding when to copy others and whom to copy. Furthermore, some researchers are interested in assessing how important social learning is in determining the behavioral repertoires of animals in their natural environment, and the circumstances under which social learning results in animal culture.

## Social Network Analysis

Sebastian Sosa

Anthropology Department, School of Sociology and Anthropology, Sun Yat-sen University, Guangzhou, China

## Introduction

Social network analysis (SNA) originates from a branch of mathematics called graph theory. This disciplinary field has developed several concepts and analytical methods that permit the study of links between the components of a system. SNA is the result of multiple studies from different research fields and particularly from social sciences such as psychology, sociology, and anthropology.

The SNA approach has facilitated the study of many other subjects in a large variety of disciplines such as anthropology, mathematics, economics, psychology, ethology, ecology, sociology, computer sciences, physics, epidemiology, cell biology, and biochemistry (Prell 2011).

This entry is divided into three sections that can be read separately according to the reader's needs:

1. Section 1: description of the use of SNA tools in life science, highlighting the great potential of these techniques across a wide range of animal research topics
2. Section 2 to Section 4: a thorough technical presentation of SNA to inform readers about the most commonly used network metrics and provide guidelines to obtain reliable statistics
3. Section 5: an example based on Hinde's conceptual framework illustrating the new prospects opened up by SNA techniques for the study of animal societies and providing recent examples of their use

### Social Networking in Biology: From Genes to Animal Societies

Since the early 2000s, the use of SNA techniques by researchers from different biology fields has led to the emergence of a universal approach.

Genetics researchers have used SNA to study gene interactions in regulatory systems. For example, researchers in autism spectrum disorder (ASD) examined protein interaction networks and the co-expression of genes between these interacting proteins (LaFlamme 2015). This study identified the coding variants that are responsible for the communication between the two brain hemispheres in individuals with ASD.

Neuroscientists have used SNA to study brain disorders such as epilepsy through dynamical network modeling in order to identify the mechanisms triggering a stroke and the neuronal network responsible for a stroke in patients in order to remove it surgically (Jirsa et al. 2010).

SNA techniques are widely used in the epidemiology field. Researchers have used social network analysis to predict and control the spread of diseases in periods of epidemic crises such as the Ebola outbreak in West Africa between 2014 and 2016. Mathematical and computational methods now play a major role in epidemics modeling through the theoretical framework of host population transmission dynamics. This disciplinary field is not restricted to human study but also applies to animal research: researchers evidenced a link between individual centrality and the transmission of infections in nonhuman primates (see the “► [Nonhuman Primates](#)” entry of the

encyclopedia for more details), in which centrality accelerated and widened the spread of disease, with the most central individuals being infected more quickly than less central ones (Romano et al. 2016).

The study of virus transmission within a network is akin to the study of the spread of information. Thus, using similar analytical techniques, some studies attempted to understand the spread of information in domains such as novel behaviors (see the “► [Cultural Transmission](#),” “► [Diffusion](#),” “► [Social Learning](#),” and “► [Innovation](#)” entries of the encyclopedia for more details) and terrorist communications. However, specific statistical techniques have been developed to study the spread of information in social networks, such as the network-based diffusion approach (NBDA). These techniques consist in modeling the spread of information transmission along the network links. For an overview of these techniques, see Hoppitt and Laland (2013). NBDA has greatly influenced the study of animal social transmission, and it allowed, among other things, to reveal that a special fishing technique called “lobtail feeding” observed in humpback whales was socially spread and maintained in the population for 27 years, showing the presence of animal culture in this cetacean species (Allen et al. 2013).

SNA approaches also permit the study of diverse systems from an evolutionary perspective and are widely used in ecology (see the “► [Ecology](#)” entry of the encyclopedia for more details). Ecology is a huge disciplinary field, where SNA is used across the range of disciplines from behavioral ecology, where it revealed a relationship between individual fitness (see the “► [Fitness](#)” entry of the encyclopedia for more details) and individual ego-network (Cheney et al. 2016), to the study of ecosystem and community structures, where its use pinpointed a clear link between network modularity and network size and highlighted the presence of very few indispensable species for the network structure in plant-pollinator networks (Olesen et al. 2007).

The study of animal behavior is also a wide disciplinary field that considers domains ranging from proximal mechanisms (i.e., factors that

trigger a behavior) to phylogeny through ontogeny and the influence of behaviors from an evolutionary perspective. SNA is used when ethology interlinks with other fields such as genetics, neurosciences, and ecology (Sueur et al. 2011a).

SNA is obviously an ideal tool for the study of animal societies (Whitehead 2008). Indeed, SNA gave rise to a novel perspective of the field of sociobiology, which is further discussed in the section “[An Example of Research into the Power of Social Networking in Animal Societies.](#)”

This non-exhaustive list of biology disciplines using social networking tools gives a glimpse of the huge potential of SNA. Many other fields make use of these tools, using it for unexpected purposes such as studies in plant biology (see the “[► Plantae](#)” entry of the encyclopedia for more details) that reveal the ability of intra- and inter-specific plant networks to cooperate by sharing nutrients and water through mycorrhizas (see the “[► Symbiotic Relationship](#)” entry of the encyclopedia for more details) (Egerton-Warburton et al. 2007).

### Social Networking in Animal Research: Some History

The first animal studies to use SNA were carried out at the end of the 1960s and the beginning of the 1970s. Primatology studies that were pioneers in the use of SNA (Wey et al. 2008) used sociograms to represent individual interactions. This representation allows the identification of existing and nonexistent interactions between dyads (i.e., a pair) of nodes but also highlights hierarchical clustering and provides a multidimensional scale, all necessary for the study of group divisions according to given relationships (Wey et al. 2008).

Subsequent studies focused on the measurement of individual sociability (degree, clustering coefficient, eigenvector, centrality, etc.) as an indication of an individual's position within the network, for example, through the individual comparative study of interactional frequency according to different factors such as individual attributes, hierarchical rank (see the “[► Dominance](#)” and “[► Dominance Hierarchy](#)” entries of the encyclopedia for more details), or kinship (see

the “[► Kinship](#)” entry of the encyclopedia for more details) (Berman 1982; Wey et al. 2008).

These techniques have been increasingly used over the last 15 years. The enhancement of computing power in the late 1990s and early 2000s facilitated randomization testing and the analysis of large networks and boosted the use of social networking tools in biology. A boom has since been witnessed in the number of studies using these tools for different purposes, some of which have been described in section “[Social Networking in Biology: From Genes to Animal Societies.](#)”

### Principle

A network is defined as a set of connections (*links* or *edges*) between a set of components (*nodes* or *vertices*). This representation aims to describe the state of a complex multi-relational system as fully as possible at a given time and in a given space.

The nodes can be individuals, groups of individuals, species, cells, molecules, websites, and companies, to name but a few. Nodes can include additional information (*node label*) such as age, sex, kinship, social role, socioeconomic characteristics, etc. A focal node is called *ego*, the nodes to which the ego is connected are called *alters*, and the network formed by an ego and its alters is called the *ego-network*. The ego-network is defined at different levels: the first only takes into account the links between the ego and its alters, the second additionally takes into account the links between alters, and the third adds the links between alters' alters, and so forth as the levels increase.

Links can vary in nature and can be any conceivable type of behavior (among others, agonistic (see the “[► Agonistic Behavior](#)” entry of the encyclopedia for more details) and affiliative behaviors (see the “[► Affiliative Bond](#)” entry of the encyclopedia for more details)) and relationship (friendships, sexual partnerships, etc.). Links can include additional information such as their weight; in this case it is then referred to as a *weighted* network (values range from 0 to infinite), as opposed to a *binary* network (values range from 0 to 1). In animal research, the weight

of the links can represent data such as the frequency of interaction between two nodes (e.g., individual A groomed – see the “► [Allogrooming](#)” entry of the encyclopedia for more details – individual B for 10 times) or the duration of the interaction (individual A groomed individual B for 10 min). Links can also have directions, in which case the network is considered to be *directed* rather than *undirected*. With a directed network, it is possible to indicate the direction of an interaction (individual A groomed individual B, individual C attacked individual D, etc.). Undirected networks can be used to represent interindividual distances, for example, individual A was 5 m away from individual B. It is also possible to create links with negative weights or to represent different types of links within a network, thus forming a *multiplex network*. However, *multiplex networks* are rarely used in animal research. Thus, these techniques will not be discussed in this entry.

## Network Metrics

Several analytical methods have been developed to study the different aspects of a network. These methods can be divided into three main categories: global metrics, dyadic metrics, and node metrics. The large range of existing tools permits a multilevel study of a network and thus provides an approach that covers all network aspects from the nodes to the way they interact between each other and finally how these two sublevels affect the overall network structure.

A high number of network metrics are currently available. This entry introduces the most commonly used network metrics in animal research, including a description of the different versions. The investigator can then choose the most appropriate version for the measure he/she wants to obtain and should be careful to select a version that suits the context. For each of these metrics, the following elements will be provided: the mathematical formula, their purpose, their limits, their strengths, precautions that must be taken when using them, and their use in animal research.

## Global Metrics

Global metrics aim to describe the global structure of a network by providing information about questions such as its resilience properties (i.e., the network's capacity to remain undisrupted if nodes are lost), clusterization (i.e., the network is structured in subgroups), or the speed of information transmission. Global metrics can be measured across the entire network or by partitioning the overall network into ego-networks for metrics such as density, diameter, etc.

### Density

The density of a network is simply the ratio of existing links of a network in relation to all potential links (Eq. 1). For a binary network  $G$  with  $N$  nodes and  $L$  links, the density ( $D^b$ ) is

$$D^b(G) = \frac{2|L|}{|N|(|N| - 1)} \quad (1)$$

Density is basic, useful, and easy to interpret. However, special consideration must be taken when examining a network, as this metric strongly affects many aspects of the network and is influenced by (1) the size of the network and (2) the sampling effort. Density is linked to degree distribution. It affects geodesic distances and it is positively correlated to the likelihood of observing micro-motifs (substructures of a network) like “closed triplets” (i.e., three nodes connected to each other) and thus the increase of the clustering coefficient (see section “[Global Clustering Coefficient](#),” for a definition) and other network metrics such as node degree diversity.

These constraints mean that great care must be taken when comparing networks from different groups and species, observed at different moments and/or with different sampling efforts. There is no analytical protocol available to deal with such network constraints. Some network metrics (like modularity) or third- or fourth-order node network metrics do seem less affected by these constraints, but these are not used in animal research and are not therefore discussed in this entry.

Density is generally used as a network descriptor in animal research. However, recent studies

have linked density to different factors such as living condition (wild or captive) or group size. For example, Balasubramaniam et al. (2017) found greater density in captive groups of macaques than in wild groups. Such comparison is possible by using a Bootstrapping approach to control the effect of density variation on the real networks (i.e., by removing links and repeating the comparison) by simulating variations in sampling effort degrees.

### Geodesic Distances

Geodesic distances are the shortest paths to reach all possible pairs of nodes in a network. Several algorithms can be used to find these paths, including the breadth-first search for unweighted networks, Dijkstra's algorithm for weighted networks, and the Bellman-Ford-Moore algorithm for weighted networks with positive and negative weights.

This metric can be calculated in binary or weighted networks and for directed or undirected networks. Although geodesic distance is a well-known network metric, results might vary according to the calculation process, and it is only recently that calculations have been developed to consider the highest strength as the shortest path in weighted networks (Opsahl 2009). Previously, the links with weakest strengths were considered the fastest ones. Therefore, it may be inappropriate to use the latter version on a weighted graph when examining disease transmission, as the probability of transmission can be proportional to the individuals' strength of interaction (Krause et al. 2014). Obviously, directionality may also be an important option to consider when examining disease transmission.

Although the geodesic distance may be useful in the study of epidemiology, it remains poorly used in animal research due to its high sensibility to observation biases (unobserved interactions, misidentification of individuals, etc.) (Krause et al. 2014).

### Diameter

The diameter is simply the longest geodesic distance (i.e., the longest of the shortest paths) of a

network. Here again, it can be calculated on binary or weighted networks and for undirected or directed networks. Depending on the problematic, care is necessary when choosing the calculation method (binary or weighted, directed or undirected) and using the lowest or the highest strength as the shortest path, as explained in section "Geodesic Distances."

The diameter most certainly owes its fame to the works of Milgram (1967), who sent a letter addressed to a specific recipient to random people living in the United States with the aim of reaching the recipient via these people. An average of six people was required in the resulting human chain from the sender to the intended recipient. This experiment gave rise to the theory of the "small-world effect." The Internet and the many associated social networks such as Facebook and Twitter have decreased the degree of separation between American people from six to four individuals (Backstrom et al. 2012).

Diameter is used in animal research to examine issues such as the resilience of a network or the information transmission. For example, through target deletion simulation of individuals with high centrality (see section "Node Metrics"), several studies have highlighted the key role played by individuals with high centrality (degree, eigenvector, etc.) in the cohesion of affiliative networks in dolphins, Colombian squirrels, killer whales, and primates, among others (see Sosa (2014) for more details).

### Global Clustering Coefficient

The global clustering coefficient measures the extent to which nodes in a network are connected together. As several definitions of this metric can be found in the literature, careful attention must be paid when using a software, as different definitions can apply. One of the simplest definitions is the binary global clustering coefficient (Eq. 2) for a binary network that is the ratio of closed triplets to all triplets (open and closed) in a network. Triplets are three nodes connected by two or three undirected links (open or closed triplets, respectively). For a graph  $G$ , the binary global clustering coefficient ( $C^b$ ) formula is the following:

$$C^b(G) = \frac{\sum \tau_{\Delta}}{\sum \tau} \quad (2)$$

where  $\sum \tau$  is the total number of triplets (open and closed) and  $\sum \tau_{\Delta}$  is the subset of closed triplets.

Another version of the clustering coefficient is derived from the local (i.e., node) level: it is called the local mean clustering coefficient (Eq. 3). The local clustering coefficient will be further detailed in section “[Node Metrics](#).” For a network  $G$  with  $N$  nodes  $i$ , the clustering coefficient ( $\bar{C}^b$ ) is defined as the mean of all node clustering coefficients ( $C_i$ ):

$$\bar{C}^b(G) = \frac{1}{N} \sum_{i=1}^N C_i \quad (3)$$

The Barrat et al. (2004) clustering coefficient (Eq. 4) is one possible weighted version of this local mean clustering coefficient. It is also derived from local level and is based on a weighted version of all node clustering coefficients ( $C_i^w$ ). This node metric will be described in greater detail in section “[Node Metrics](#).” For a network  $G$  with  $N$  nodes  $i$  and  $n$  alters  $j$ , the weighted clustering coefficient ( $C_{nn,i}^w$ ) formula is the following:

$$C_{nn,i}^w(G) = \frac{1}{s_i} \sum_{j=1}^n a_{ij} w_{ij} D_i \quad (4)$$

where  $s_i$  is the strength of node  $i$  (see section “[Degree and Strength](#),” for a definition),  $a_{ij}$  is the link between node  $i$  and alter  $j$ ,  $w_{ij}$  are the weights of this link between node  $i$  and alter  $j$ , and  $D_i$  is the degree of node  $i$  (see section “[Degree and Strength](#),” for a definition).

Another weighted version of the global clustering coefficient (Opsahl 2009) (Eq. 5) considers the triplet value  $\omega$  selected according to its most appropriate meaning, namely, the maximum or minimum values of the weights or the arithmetic or geometric means of the weights of the links in a triplet. For a graph  $G$ , the weighted global clustering coefficient ( $C^w$ ) formula is the following:

$$C^w(G) = \frac{\sum \tau_{\Delta} w}{\sum \tau_{\Delta} w} \quad (5)$$

where  $\sum \tau$  is the total number of triplets and  $\sum \tau_{\Delta}$  is the subset of closed triplets.

This is not a complete list of the many versions of the global clustering coefficient. The investigator may therefore choose the most appropriate version as it may lead to different biological interpretations.

The clustering coefficient is a very important metric for the evaluation of “transitivity” and related concepts (see section “[Transitive Triplets](#)”), as it indicates how well the alters of an ego are interconnected. The clustering coefficient promotes the cohesion of the network. This has been illustrated by works showing that “policing” individuals (i.e., individuals that regularly intervene as third parties in conflicts) are largely responsible for increased global clustering coefficient in nonhuman primate societies (Flack et al. 2006), revealing the important role these individuals play in network group cohesion.

#### Network Clusterization

Network clusterization, or *subgrouping*, strongly influences the resilience properties of the network and the speed of information transmission. Understanding how a network is clustered and identifying which nodes form the cluster and how different clusters are linked is a critical question for community detection in ecology, wildlife preservation, and research on societies.

The study of the existence of subgroups within a network is a wide research area that has produced a large variety of clusterization techniques including K-means, hierarchical clusterization, and Girvan-Newman algorithms. Some of them base the algorithms on node network metrics, like modularity with eigenvector (Newman 2006). Others are based on micro-motifs such as closed triplet, as seen in the conductance motif approach (Tsourakakis et al. 2017).

The definition of a subgroup itself can be viewed in different ways. For example, a subgroup can be considered a set of nodes where everyone is connected (a subgroup of density 1): this is referred to as a clique (Hanneman and Riddle 2005). However, cliques are restrictive, as some nodes may not be completely connected

to the other nodes of the group and can therefore be omitted. This restricted definition has several variants with less stringent applications, such as N-cliques (Hanneman and Riddle 2005). N-cliques consider a node to be a member of a subgroup if it is connected to all the other members of the group at N distance (generally defined by the user). N-clans (Hanneman and Riddle 2005) are similar to N-cliques but with the restrictive condition that all the links among members of the N-clique occur via other members of the N-clique. This subgroup definition can be developed further with K-plexes or with K-cores and F-Groups (Hanneman and Riddle 2005).

The choice of the technique used is left to the user, who has to consider which approach is more suitable according to the question and to the biological interpretation that may be extracted.

Modularity is one of the most commonly used network cluster measures today and may be linked to several biological aspects such as social-style dependent modularity differences in macaques, where despotic societies (i.e., species with high levels of social intolerance, steep dominance gradient, and strong kin preference) show higher modularity than egalitarian societies (i.e., species with high levels of tolerance, relaxed dominance, and low kinship bias). Higher modularity in despotic societies seems to be related to preferential interactions with kin, leading to the formation of clusters based on kinship bonds.

### Dyadic Metrics

Dyadic metrics make it possible to examine how and with whom individuals interact, revealing patterns of interaction. These metrics deeply impact the development of the global network structure through the repetitive nature of these local patterns, which form the overall global network structure to a certain extent. This entry will discuss two of the dyadic metrics that are increasingly used in animal research, explaining their impact at the global structure level and discussing the parallels that can be drawn between the presence of those dyadic metrics and the presence of biological phenomena.

### Assortativity

Assortativity (Newman 2003) (like the E-I index or the Moran “I” statistic) allows the study of homophily (preferential interaction between nodes with similar attributes) and heterophily (the preferential interaction between nodes with different attributes) (Lazarsfeld and Merton 1954). Attributes can be individual characteristics such as sex or age or individual node metrics such as the degree (see section “Degree and Strength,” for a definition), in which case it is referred to as *assortativity by vertex degree*.

The assortativity coefficient, like other metrics that analyze homophily, basically measures the proportion of links between and within nodes of specific attributes. The assortativity range is as follows:  $1 > r > -1.1$  indicates that the network is fully assorted (i.e., all the nodes of same attributes interact exclusively together), and  $-1$  shows that the network is fully disassorted (i.e., all the nodes of dissimilar attributes interact exclusively together). There are four types of assortativity coefficient according to the type of node attributes (categorical or continuous) and the type of network (binary or weighted).

For a network  $G$ , the binary discrete assortativity coefficient ( $r_d^b$ ) (Newman 2003) (Eq. 6) formula is as follows:

$$r_d^b(G) = \frac{\sum_i e_{ii} - \sum_i a_i b_i}{1 - \sum_i a_i b_i} \quad (6)$$

where  $e$  is the proportion of specific links in the network,  $e_{ii}$  is the number of links between nodes of attributes  $i$  ( $E_{ii}$ ) divided by the total number of links in the network  $M$ :  $e_{ii} = M^{-1} \cdot E_{ii}$ ,  $a_i$  is the proportion of outgoing links from nodes of attributes  $i$  toward all possible nodes of attributes  $j$ :  $a_i = \sum_j e_{ij}$ , and  $b_i$  is the proportion of all possible outgoing links from nodes of attributes  $j$  toward nodes of attributes  $i$ :  $b_j = \sum_i e_{ij}$ .

For a network  $G$ , the weighted discrete assortativity coefficient ( $r_d^w$ ) (Eq. 7) formula is as follows:

$$r_d^w(G) = \frac{\sum_i e_{ii}^w - \sum_i a_i^w b_i^w}{1 - \sum_i a_i^w b_i^w} \quad (7)$$

where  $e_{ii}^w$  is the proportion of weighted links between nodes of attributes  $i$  divided by the total number of links in the network,  $a_i^w$  is the proportion of the outgoing weighted links from nodes of attributes  $i$  toward all possible nodes of attributes  $j$ :  $a_i^w = \sum_j e_{ij}^w$ , and  $b_i^w$  is the proportion of all possible outgoing weighted links from nodes of attributes  $i$  toward nodes of attributes  $j$ :  $b_i^w = \sum_j e_{ij}^w$ .

For a network  $G$ , the binary continuous assortativity coefficient ( $r_c^b$ ) (Newman 2003) (Eq. 8) formula is as follows:

$$r_c^b(G) = \frac{\sum_i (j_i k_i) - M^{-1} \sum_i j_i \sum_i k_i}{\sqrt{[\sum_i j_i^2 - M^{-1} (\sum_i j_i)^2][\sum_i k_i^2 - M^{-1} (\sum_i k_i)^2]}} \quad (8)$$

where  $j_i$  and  $k_i$  are the node labels of the  $i^{\text{th}}$  in-degrees and out-degrees, respectively, and  $M$  is the total number of links.

For a network  $G$ , the weighted continuous assortativity coefficient ( $r_c^w$ ) (Leung and Chau 2007) (Eq. 9) formula is as follows:

$$r_c^w = \frac{\sum_i (w_i j_i k_i) - W^{-1} \sum_i (w_i j_i) \sum_i (w_i k_i)}{\sqrt{[\sum_i (w_i j_i^2) - W^{-1} (\sum_i (w_i j_i))^2][\sum_i (w_i k_i^2) - W^{-1} (\sum_i (w_i k_i))^2]}} \quad (9)$$

where  $j_i$  and  $k_i$  are the node labels of the  $i^{\text{th}}$  in-strengths and out-strengths, respectively,  $w_i$  is the weight of link  $i$ , and  $W$  is the sum of all the weights of all network links.

At a network level, assortativity leads to more clustered and resilient networks (Newman 2003). From a biological perspective, recent studies argue that preferential interactions among individuals sharing a common attribute (i.e., homophily) may explain the difference observed between animals and humans for cooperation among strangers, social learning, and the transmission of culture and norms (Allen et al. 2013; Sosa et al. 2017). Homophily according to different phenotypes (such as sex, age, kinship, degree, or

weight) was found in several species including fish, birds, cetaceans, and primates.

### Transitive Triplets

Another dyadic metric recently investigated in animal research is the micro-motif called transitive triplets. Its creation process reveals a phenomenon called “triadic closure” which indicates an individual preference to create links with individuals who are connected to individuals they already know. This dynamic behavioral pattern is generally described as “the friend of my friend is my friend,” and it is characterized by transitive triplet micro-motifs in a network.

The main topological effect of triadic closure is the clusterization of the network. The triadic closure process may also be a mechanism enabling network degree assortativity, i.e., individuals interact in a preferential way with individuals of the same degree, which is a key element in social network resilience (Newman 2003).

From a biological perspective, transitive triplets generate cohesive groups and seem to be intimately linked to the emergence of reciprocity, altruism, and cooperation (see the “► [Cooperation](#)” and “► [Reciprocity](#)” entries of the encyclopedia for more details).

The presence of this mechanism has recently been highlighted in several animals such as corvids, hyenas, and nonhuman primates (Sosa et al. 2017). As seen for homophily, transitive triplets not only highlight a common mechanism between humans and animals providing information about evolutionary aspects, but they also reveal how individuals extend their ego-network according to these behavioral patterns (Sosa et al. 2017).

### Node Metrics

Node metrics are calculated at a node level. They are simply based on ego: these are first-order metrics. Other metrics are based on ego and alter measures, such as second-order metrics. This type of metric allows researchers to analyze different aspects of a node, including the number of links it has, its centrality (i.e., a central node is well connected and/or is connected to well-connected nodes), or its role in maintaining network cohesion, for example.

### First-Order Metrics

There are very few first-order metrics, owing to the limitations of considering the links of only one node. Therefore, second-order metrics were rapidly developed to determine the type of alters to which a node is connected.

**Degree and Strength** First-order metrics are simple, like the degree (Eq. 10) that measures, for example, the number of links of a node in a binary network. If the network comprises directed links, it is then possible to differentiate between the incoming links (i.e., links directed toward the ego, also called *in-degree*) and the outgoing links (i.e., links emitted by the ego, also called *out-degree*). For a node  $i$  with  $N$  alters  $j$  in a network  $G$ , the degree ( $D_i$ ) formula is as follows:

$$D_i(G) = \sum_{j=1}^N a_{ij} \quad (10)$$

where  $a_{ij}$  is the value of the link between node  $i$  and node  $j$ .

If the network is weighted, then the degree is called *strength* or the *weighted degree* (Eq. 11). If the network comprises directed links, then it is also possible to differentiate between the incoming links (in-strength) and the outgoing links (out-strength). For a node  $i$  with  $N$  alters  $j$  in a network  $G$ , the degree ( $S_i$ ) formula is as follows:

$$S_i = \sum_{j=1}^N a_{ij} w_{ij} \quad (11)$$

where  $a_{ij}$  is the link between node  $i$  and alter  $j$  and  $w_{ij}$  is the weight of this link.

Degree and strength are very simple and can easily be used to interpret node network metrics. Their interpretation varies depending on the type of edges and can be perceived as the activity (i.e., total frequency of expression of a behavior) or the centrality (i.e., whether a node is poorly or highly connected) of a node. When considering the directionality of edges, in-degree is often used as a measure of popularity and out-degree as a measure of expansiveness. These simple metrics

constitute the basis for calculating most of the other more complex metrics, as detailed in the following sections.

Degree is one of the most appropriate measures to study epidemiology due to its low sensitivity to observation biases, unlike geodesic distance and related node metrics (Krause et al. 2014). A link has been evidenced in epidemiology research between degree and parasite load. At a species level, host infection can be significantly linked to the in-degree, as seen in lizards, or to the out-degree, as observed in Japanese macaques (see Krause et al. (2014)).

### Second-Order Metrics

Second-order metrics allow to take the metrics of ego alters into account and thus make it possible to analyze different aspects of a node, such as its position within the network (e.g., closeness or betweenness) or its centrality (eigenvector centrality, reach, disparity, etc.). For example, it is not the same to be connected to the most central node in the network as it is to be connected to a peripheral node. Similarly, it is not the same to be connected to a few extremely central nodes as it is to be connected to many peripheral nodes.

**Eigenvector Centrality** Eigenvector centrality (Eq. 13) is the first nonnegative eigenvector value obtained through the linear transformation of an adjacency matrix. This centrality measure quantifies not only a node's connectedness but also the connections of the nodes to whom it is connected (i.e., ego's alters' centralities). Thus, a node can have a high eigenvector value by having a high degree or strength or by being connected to nodes that have high degrees or strengths.

For a network  $G$ , the centrality  $c_i$  of a node  $i$  is the average of its alters' centralities (Eq. 12) and is calculated with the following formula:

$$c_i = \frac{1}{\lambda} \sum_{j=1}^N w_{ij} c_j \quad (12)$$

where  $\lambda$  is a constant,  $N$  is the number of alters of  $i$ , and  $w_{ij}$  is the link between  $i$  and the  $j^{\text{th}}$  alter.

Defining the vector of centralities as  $c = (c_1, c_2, \dots, c_N)$ , Eq. 12 can be rewritten as follows:

$$\lambda c = Wc \quad (13)$$

where  $c$  is the eigenvector of the edge weight matrix  $W$  with an eigenvalue of  $\lambda$ . If only the positive eigenvectors are considered, then only the largest eigenvalue provides the eigenvector centrality.

Eigenvector is one of the most frequently used second-order metrics in animal research and is linked to several biological aspects such as individual fitness (see section “[Micro Level: Individual Position, Role, and Fitness](#)”), genetic variation (see Krause et al. (2014)), or individual attributes. For example, the eigenvector centrality of female affiliative networks in despotic macaque societies is related to the hierarchical ranks of females, unlike in egalitarian societies (Sueur et al. 2011b), and thus reveals a link between social style and network structure.

**Reach** Reach (Eq. 14) is a measure of indirect connectedness (Whitehead 2008). As eigenvector centrality, it measures how well connected a node and its alters are. It can be calculated on binary or weighted networks. The binary version is simply the number of alters of a node  $i$  at level one (the degree in this case) or more. For a node  $i$  of  $N$  alters  $j$  in a network  $G$ , the binary reach index ( $r_i^b$ ) formula is as follows:

$$r_i^b(G) = j_1 + j_2 + \dots + j_N \quad (14)$$

The weighted version (Eq. 15) is the sum of the product of all the ego and alters’ strengths and the alters’ degrees. For a node  $i$  of  $N$  alters  $j$  in a network  $G$ , the weighted reach index ( $r_i^w$ ) formula is as follows:

$$r_i^w = \sum_{j=1}^N a_{ij} S_j \quad (15)$$

where  $a_{ij}$  is the weight of the link between node  $i$  and node  $j$  and where  $S_j$  is the strength of node  $j$ .

Reach is a useful measure when examining contagion processes, as it allows investigators to highlight the pathway of information through direct connections. Studies have shown that differences across individual reach metrics might be related to individual roles. For example, node deletion simulations by Flack et al. (2006) showed that “policing” individuals had higher reach values than other group members in a group of *Macaca nemestrina*, thus facilitating their role in policing conflicts.

**Node Betweenness** Betweenness is the number of times a node is included in the shortest paths (geodesic distances) between all the potential combinations of edges of the other nodes. As it is directly derived from the geodesic distance, it is important to pay attention to how the investigator intends to calculate the geodesic distances (binary or weighted, directed or undirected, and using the lowest or the highest strength as the shortest path). Betweenness provides a specific centrality measure insofar that it informs on the role of a node in the transmission of information as nodes with high betweenness are likely to constitute bridges that connect subgroups.

Like geodesic distance, betweenness may be useful in the study of epidemiology. However, it is not frequently used in animal research due to its high sensitivity to observation biases (unobserved interactions, misidentification of individuals, etc.) (Krause et al. 2014).

**Local Clustering Coefficient** Like the global clustering coefficient ( $C$ ) described in section “[Global Clustering Coefficient](#),” the local clustering coefficient of a node ( $C_i$ ) is defined in several different ways in the literature. It attempts to determine the connections between the alters of an ego and indicates whether they tend to interact or not, forming a network with a greater or lesser density which contains more or less transitive triplets. This can impact the network in different ways, affecting resilience (theoretically, a dense network is more resilient than a less dense network of the same size) or the transmission of information (theoretically, transmission is faster

in a dense network than in a less dense network of the same size).

The local clustering coefficient is the proportion of links between the nodes of an ego-network divided by the number of potential links between them; it can be defined as the density of an ego-network. As discussed in section “[Global Clustering Coefficient](#),” it allows the calculation of the local mean clustering coefficient. Like density, it evaluates how close nodes’ ego-networks are to a clique (i.e., a fully connected ego-network of density 1). For a node  $i$  with  $N$  alters  $j$  in a network  $G$ , the binary local clustering coefficient of  $i$  ( $C_i^b$ ) (Eq. 16) is defined as

$$C_i^b = \frac{2t_i}{N_i(N_i - 1)} \quad (16)$$

where  $t_i$  is the number of links present in the ego-network of node  $i$ .

The Barrat et al. (2004) (Eq. 17) clustering coefficient is one possible version of the local clustering coefficient for use in weighted networks. For a node  $i$  with a pair of alters  $j$  and  $h$  among  $N$  alters, the weighted local clustering coefficient of  $i$  ( $C_i^w$ ) is defined as

$$C_i^w = \frac{1}{S_i(D_i - 1)} \sum_{j \neq h \in N} \frac{(w_{ij} + w_{ih})}{2} a_{ij}a_{ih}a_{jh} \quad (17)$$

where  $S_i$  and  $D_i$  are, respectively, the strength and the degree of node  $i$ ;  $w_{ij}$  and  $w_{ih}$  are the weights of the links between node  $i$  and, respectively, alter  $j$  and alter  $h$ ; and  $a_{ij}$ ,  $a_{ih}$ ,  $a_{jh}$  are, respectively, the links between node  $i$  and alters  $j$  and  $h$ .

The clustering coefficient is both a local and a global metric (see section “[Global Clustering Coefficient](#)”) that permits the examination of how local motifs affect the overall network structure. For this reason, it has been widely used to study epidemiology in animal networks. One such example is the demonstration of interactional adaptive capacity to infectious disease in guppies. In this study, lower local clustering coefficients were recorded in groups to which infected individuals had been introduced than in the control

group (to which no infected individuals had been introduced). This reveals that individuals actively adapt their behaviors to prevent disease infection (Croft et al. 2011a). These interactional patterns directly affect the overall network structure through the decrease in the global clustering coefficient. The fact that networks with a low global clustering coefficient are more resilient to the spread of infectious diseases highlights how local interactional patterns shape the overall network structure and provide it with dynamical adaptive properties.

### Specific Points to be Considered Within the SNA Research Context

For decades, null hypothesis significant testing (NHST) (Anderson et al. 2000) has been widely used in research for testing binary hypotheses ( $H_0$  vs.  $H_1$ ). All of these hypotheses postulate that data are independent, and they examine whether these data are significantly different from zero. However, data from social groups are intrinsically non-independent, as links within the network are shared between nodes. Two approaches deal with this dilemma: one is based on the null model hypothesis (NMH) (Croft et al. 2011b; Farine 2017), and the other is based on simulations. The first one consists in creating random networks and then compares them to the real one. The second one simulates the processes involved in the formation of links, then creates networks from these simulations, and finally compares these simulated networks to the real one.

#### Null Model Hypothesis

The NMH approach consists in creating a random dataset from the observed data. The randomized data have to conserve the same structure as the original data, except for those the investigator wants to test. The metrics of interest  $X$  of the observed data and the posterior distribution issued from the randomization are then compared to examine if they are significantly different by assessing the proportion of random values that differ from the observed values. Through this approach, the investigator tests whether  $X$  are

different to random values instead of testing if they are different to zero.

There are two ways of categorizing NMH: firstly, according to the elements of the network that are being resampled (links or node labels), and, secondly, according to whether they are built on raw data (before building the network: pre-network randomization) or on the network (after building the network: network randomization).

### Randomization

Randomization approach consists in randomizing link and/or node labels in a network. Link randomization (i.e., permuting links between each other) maintains the number of links. This approach is mainly used for the analysis of interactional patterns, i.e., how interactions are arranged and which individuals are involved. Node label randomization consists in permuting node characteristics, thereby preserving the structure of node links. The objective of such approach is to determine whether a node's position is linked to its intrinsic characteristics.

#### Network Randomization

Network randomization is used when examining direct behavioral interactions and when groups are well defined. This approach consists in randomizing link or node labels directly on the observed network. When links refer to individuals' association (i.e., spatial proximity, group composition, etc.), a pre-network randomization is necessary.

#### Pre-network Randomization

Permutations on raw data use a permutation process, first created by Bejder et al. (1998) and further improved (see Farine (2017) for an overview). Also called data stream permutations, this process consists of running a permutation on raw data and then building the network with this permutation, so the metric of interest can be measured again. This process is repeated as many times as needed (generally 1000 or 10.000 permutations) until the required number of permutations is complete. Pre-network randomization is mainly used in ecology when interindividual links are inferred by individual

associations. It is then referred to as the “gambit of the group.” This principle is based on the likelihood that individuals who frequently gather will interact with each other. It is then possible to infer preferential interactions from the presence/absence of certain individuals. For this process, it is important to consider not only the size of the group observed but also the ease of observation of some specific individuals, which *in fine* influences their frequency of observation. This is why permutations on raw data are required. This type of randomization consists in link permutations. Pre-network randomization also allows to deal with several observation biases by allowing link permutations according to a given factor of interest, such as spatial structure or temporal structure, i.e., permuting links between groups according to their spatial or temporal associations. One recent improvement concerns the capacity to handle data obtained from GPS tracking in order to preserve the autocorrelation structure of individuals.

### Simulation-Based Approach

The simulation-based approach consists in simulating the formation of links in a network and in comparing the simulated networks to the real one. These techniques usually use Monte Carlo and Markov chain (MCMC) to simulate dataset according to a prior distribution. The exponential random graph models (ERGMs) (Robins et al. 2007) are among the most usual simulation-based approaches.

#### Monte Carlo and Markov Chain

The Monte Carlo (MC) process is a method that generates random samples of size  $N$  through the *expected value function*  $g$  of random variable  $x$  ( $x_0, x_1, \dots, x_N$ ). The objective is to recreate a sample size according to the mean and the variance of the observed sample (i.e., the prior distribution  $\pi$ ). Random numbers are generated through Markov chain (MC) processes. Markov chain processes are stochastic techniques in which the information that enables the prediction of the future state of a system is only present in its current state: the principle is to establish a probability distribution  $\pi_{x_{i-1}}$  that generates a resampled

dataset  $x_i$  based on the previous resampled dataset  $x_{i-1}$ .

By repeating this process, it is then possible to obtain a posterior distribution of the parameter of interest according to the resamples. MCMC technique can be used for both simulation and randomization approaches. Contrary to randomization approach, the use of MCMC in a simulation approach has the advantage of assessing several statistical measures such as the standard deviation or the confidence interval for the parameter of interest. MCMC technique represents the core of Bootstrapping and Bayesian approaches.

### Exponential Random Graph Models

ERGMs constitute a family of statistical models based on network simulations. This approach formulates the probability of observing links through an MCMC-based maximum likelihood estimation according to different structural mechanisms. The latter can be node based (i.e., how nodes' attributes affect the formation of a new link), dyadic (i.e., how the other links affect the formation of a new link), or structural (i.e., how some network structures affect the formation of a new link). These models permit the study of binary, weighted, and dynamic networks.

By simulating networks according to some factors (node based, dyadic, structural), ERGMs allow to examine whether the simulated networks are significantly different from the observed network.

## An Example of Research into the Power of Social Networking in Animal Societies

Section “[Social Networking in Biology: From Genes to Animal Societies](#),” showed a wide range of research areas that use a large variety of SNA techniques. This section covers the new highlights allowed by SNA in the study of animal societies, providing a non-exhaustive overview of the different related fields. Research in animal societies is one of the fields that mostly benefited from SNA techniques.

Group living (see the “[Group Living](#)” entry of the encyclopedia for more details) is a social

condition that has arisen independently many times throughout evolutionary history, with different degrees of specialization and complexity. Many adaptive advantages are associated with living in a group, including the optimization of foraging, collective defense of resources, increased vigilance, and a dilution effect against predation (see the “[Alarm Calls](#),” “[Cooperation](#),” “[Cultural Transmission](#),” “[Hunting](#),” “[Predation Risk](#),” “[Social Grooming](#),” and “[Vigilance](#)” entries of the encyclopedia for more details). However, group living also generates costs such as increased within-group competition for access to resources and mating opportunities and the risk of acquiring and spreading infectious diseases. In order to maintain their homeostasis, societies need a trade-off to maximize the benefits and minimize the costs. This also implies an equilibrium between the needs of each individual.

Sociobiology (see the “[Sociobiology](#)” entry of the encyclopedia for more details) considers societies in the same way that behavioral ecology considers living organisms, namely, as adaptive systems. This scientific field first appeared in the 1970s. It is an interdisciplinary field that gathers different scientific approaches including evolutionary biology, ethology, ecology, anthropology, and genetics, among others. It aims to study the way social behaviors can ensure organisms (including humans) a greater evolutionary success and thereby understand the intrinsic biological properties of animal and human societies.

Animal societies can thus be viewed as systems whose adaptive properties arise from the continuous evolution of the different selective pressures that rule them. With this approach, it is possible to consider that individuals show behaviors that aim to optimize their chance to reach a better position within society, thus attaining a higher survival and reproductive rate.

In the 1970s, Hinde conceptualized the structuring of a society (Fig. 1) (Hinde 1976). The first level, which can be called the “micro level,” contains the individuals that compose the society. Individuals can be characterized by the attributes that influence their behaviors and interactions (agonistic, tolerant, affiliative, etc.). At the second

**Social Network Analysis, Fig. 1** An example of multilevel approach allowed by social network analysis in animal societies research. This scheme is inspired by Hinde (1976)

level, which can be called the “meso level,” these behaviors allow individuals to form relationships (agonistic, coalitional, affiliative, etc.). These relationships shape the final level, i.e., the “macro level.” At the macro level, the social structure can be subdivided into several substructures (hierarchical structure, affiliative structure, etc.). Together, these three levels form a society.

From this conceptual framework, a parallel can be drawn between the interest of using social networking tools and the study of animal societies, as the latter may provide new insights and new prospects for this up-and-coming field (Fig. 1).

Similarly, the different topics that can be studied using social networking tools interconnect with Tinbergen’s four questions (mechanism, ontogeny, adaptive value, and phylogeny) as explained in the following sections.

**Micro Level: Individual Position, Role, and Fitness**

Studies examining the “micro level” generally focus on describing the positions and roles of

individuals within the network according to their characteristics. There are three different possible perspectives at this level: mechanistic, ontogenetic, and evolutionary. The perspective adopted by the researcher depends on the relationship he/she seeks to highlight between the roles (in the cohesion of the network, in the spread of information, etc.) and positions (centrality, activity, etc.) of individuals and their characteristics.

The investigator’s perspective can be considered “mechanistic” when the study focuses on how roles and positions of individuals differ within the network according to social (social organization, group size, group condition, etc.) and nonsocial factors (population density, predation pressure, habitat fragmentation, etc.). This approach aims to determine the mechanistic rules underlying individual positions and roles. For example, the most active (i.e., with the highest degrees) and the most central (i.e., with the highest eigenvectors) individuals in Barbary macaques belong to the philopatric sex, i.e., females (Sosa 2016). Similar patterns have been observed in the philopatric sex in other primate

species (including macaques and baboons) and may be linked to social organization: philopatric individuals have more time to create, maintain, and expand their preferred social partnerships, making them key elements in the social structure.

The investigator's perspective can be considered "ontogenetic" when the study focuses on variation in individuals' roles and positions over their lifetimes. Due to the obvious difficulty of following groups over several generations, researchers generally focus these studies on comparing the roles and positions of individuals according to their age. Studies in primates and yellow-bellied marmots highlighted age-related variations in node network metrics (such as degree and strength), revealing a link between ontogenesis and sociogenesis: young individuals show high degrees and therefore a high number of social partners (Sosa 2016), which then decrease as individuals grow older. This may reflect a more selective choice of preferred partners as age progresses, so a trade-off is maintained between socialization and loss of resources (e.g., decline of physical and/or cognitive abilities) (Almeling et al. 2016). However, this decrease does not lead to complete desocialization as old individuals still interact with adult group members, albeit to a lesser extent (Almeling et al. 2016). These age-related variations can be examined alongside other individual attributes like sex or hierarchical rank or even kinship bonds, where individual position is transmitted from the mother to the offspring, as seen in wild crickets (Fisher et al. 2016).

Finally, the "ecological" perspective consists of linking individual node metrics and/or individual role and position to individual fitness traits, offspring fitness, spread of information, or spread of diseases. For example, the link between the sociality of a female and the survival and longevity of offspring has been amply described in social mammals such as baboons, house mice, and horses. Researchers have recently examined how far individual network metrics of a female predict the survival and longevity of her offspring. The link between node network metrics and individual fitness traits has been demonstrated in several species: betweenness in chimpanzees, clustering

coefficients in hyenas, or eigenvector centrality in juvenile dolphins (Cheney et al. 2016). For example, a long-term study by Cheney et al. (2016) on wild female baboons showed that indirect connections (measured through eigenvector centrality) affect the survival rate and longevity of their offspring more than direct connections.

### Meso Level: Individual Interaction Patterns

At the "meso level," phenomena such as homophily or triadic closure can be studied to understand how individuals create relationships. Researchers are able to examine the presence of these phenomena in a given group by using several analytical tools such as interactional metrics (described in section "[Dyadic Metrics](#)"). Understanding how individuals interact is crucial for several reasons:

1. It informs on the rules governing the expansion of individual ego-networks and therefore on how individuals create new affiliative bonds, for example.
2. It reveals interactional patterns that might reflect behavioral strategies that facilitate the acquisition of an enhanced individual position within the group, potentially improving individual fitness (see the previous section).
3. It explains overall network structures and properties, as the repetition of interactional patterns is known to have a significant effect on network structure (see section "[Dyadic Metrics](#)").
4. Some of these interactional patterns play a crucial role at ecological and evolutionary levels, as discussed in section "[Dyadic Metrics](#)." These patterns, and the role they play in phenomena such as reciprocity, could highlight underlying mechanisms that are closely linked to socialization and could be the origin of animal societies. However, this hypothesis is difficult to test and therefore remains purely speculative.

An increasing number of studies are revealing the presence of such individual interaction patterns in a wide range of species including vervet monkeys, Barbary macaques, chimpanzees, great tits, and humpback whales. One such example

is the presence of triadic closure highlighted by the presence of transitive triplets in Barbary macaques. Triadic closure is known to be closely linked to reciprocity, and, more importantly in this case, the formation of transitive triplets is not linked to individual kinship bonds. This reveals the importance of non-kin affiliative bonds in reciprocity (Sosa et al. 2017).

### Macro Level: Global Group/Network Structure

At the “macro level,” analyses focus on specific aspects of the global network structure such as network diameter, network clusterization, and degree distribution. Global network metrics are a means to study network structures, but another option is network modeling (a subject that is beyond the scope of this entry). The examination of overall network structures is of great interest as it helps to understand how they are shaped, identify their intrinsic properties, and understand how and why they differ between different species.

As mentioned in section “[Meso Level: Individual Interaction Patterns](#),” the repetition of local individual interaction patterns plays an important role in the network structure. Understanding how and to what extent sublevels shape the global network structure is crucial for obtaining knowledge on the underlying mechanisms. For example, as discussed in section “[Assortativity](#),” homophily is linked both to reciprocity and to resilience properties (Newman 2003). The fact that homophily is found in several animal societies may explain the maintenance of long-lasting bonds between conspecifics and thus also the maintenance of societies.

Network comparisons are increasingly used to understand the evolution of societies through the observation of differences across networks. This comparative phylogenetic approach highlights structural disparities that may be explained by different types of social organization or phylogeny. However, as discussed in section “[Density](#),” care must be taken when comparing biological networks in which inherent biases may occur due to group size and sampling effort, both of which affect density and thus also affect all the other network metrics.

Another promising aspect of studying network structures is the understanding of intrinsic network properties and the ability to link them to possible adaptive properties. This perspective originates from the expectations of sociobiologists, who consider societies as adaptive systems and thus observe these properties through the prism of network structure. One of the potential achievements of this approach is understanding how networks deal with the loss of central individuals. For example, Sosa (2014) showed that affiliative networks in Barbary macaques are more sensitive to the simulated loss of high-degree individuals than that of low-degree individuals. However, the network was not disrupted when 20% of the most central individuals were deleted, revealing great resilience properties that are rarely observed in artificial systems such as the World Wide Web. This finding highlights a trade-off between a centralized and a decentralized society, which are sensitive to target and random deletion, respectively. This trade-off makes sense from a selective perspective as it enables societies to maintain themselves on a geological time scale through resilience to both random and target deletions.

### SNA for a Holistic and Multidisciplinary Approach

The previous section illustrates how far SNA tools have enabled researchers to obtain valuable new insights into animal societies over the years, thus gaining a holistic understanding of structuring mechanisms of societies. This type of holistic approach does not only solely apply to sociobiology but also to many disciplines showing the huge versatility of these analytical tools (as mentioned in section “[Social Networking in Biology: From Genes to Animal Societies](#)”).

However, as observed for the maturing application of SNA in animal research, some limitations arise and may eventually require the development of means to counteract them, such as the question of comparing networks of different sizes or sampling efforts, as discussed in section “[Density](#).” Nevertheless, the continual emergence

of innovative SNA techniques leaves no doubt as to their potential to deal with these issues and to provide new insights in animal research.

## Social Ostracism

Rachel Schepke and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

### Definition

Social ostracism refers to being excluded from a group.

### Introduction

Social ostracism occurs in many species. Individuals who pose threats to a group are more likely to be ostracized. Social ostracism occurs by excluding, shunning, rejecting, ignoring, and threatening. Group members may sometimes physically assault or kill socially ostracized individuals (Goodall 1986; Lancaster 1986).

### Reasons for Social Ostracism

Individuals may be ostracized from a group or prevented from entering a group when resources

are scarce. Humans and chimpanzees reduce their group size to distribute adequate amounts of food to higher-ranking members (Benenson et al. 2008). Coalitions often ostracize and sometimes kill intruders to defend their territory (Goodall 1986; Lancaster 1986).

In several primates, individual members sometimes form coalitions and socially ostracize intruders or group members that threaten the members' social status and thereby their reproductive success. Higher-status males typically are more attractive to higher-quality females, but lower-status males may attempt to mate with these females. Male humans and other primates sometimes physically prevent lower-ranking males from mating with higher-quality females (Lancaster 1986). Higher-status males also may ostracize and otherwise exclude lower-status males from group activities in these circumstances. Among several primates, male coalitions sometimes ostracize overly aggressive males or problematic individuals who do not conform to group norms and thereby threaten group functioning (Benenson et al. 2008).

Higher-ranking females may ostracize or otherwise exclude from group activities lower-ranking females who display sexual interest in higher-ranking males (Benenson et al. 2008; Lancaster 1986). Females sometimes inflict physical harm on ostracized females but are more likely than males to ostracize other females by ignoring them, not cooperating with them, or failing to help them (Benenson et al. 2008; Wesselmann and Williams 2017).

## Negative Implications for Social Ostracism

Individuals who experience chronic ostracism – prolonged exclusion from a group – are at risk of social or physical death. Social death includes the onset of depression, anxiety, loneliness, helplessness, low self-esteem, physical health problems, and physical death (Goodall 1986; Wesselmann et al. 2012; Wrangham 2019). These negative consequences can include reduced reproductive success due to lowered fertility (White and McQuillan

2006). Regarding physical death, nonhuman animals are more likely to be killed by group members, whereas humans are more likely to commit suicide as a consequence of chronic ostracism. There is evidence that humans experience feelings of shame, embarrassment, guilt, and pain as a consequence of social ostracism; parallel feelings of distress are suspected but have not been confirmed in nonhuman animals (Wrangham 2019).

Ostracized individuals suffer costs associated with damaged social status, including reduced mating success. Higher social status predicts greater access to resources and greater mating success in humans and many other social species (Rueden and Jaeggi 2016). Thus, ostracized members not only suffer reproductive costs but also have less access to resources such as food. Individuals who develop a reputation for aggressiveness or who persistently fail to conform to group norms are more likely to be excluded from the group and, as a consequence, less likely to survive and reproduce (Wesselmann et al. 2012; Wrangham 2019).

## Tactics to Avoid Social Ostracism

Given the negative repercussions of social ostracism, individuals attempt to avoid ostracism or to gain re-inclusion into the group following ostracism through various tactics. Among humans and other species, including monkeys, wolves, birds, and other primates, individuals behave prosocially by offering parental care, cooperation, sharing, social teaching, and helping (Rault 2019; Wesselmann and Williams 2017). Prosocial behaviors benefit group members and thereby can decrease ostracism and increase the likelihood of re-inclusion in the group. Individuals also mimic other group member's behaviors, attempting to conform to group norms to avoid ostracism (Wesselmann et al. 2012).

## Conclusion

Individuals are likely to be ostracized from a group when they are an intruder, of lower status, when

there is a lack of resources, when they are perceived as a threat to other members' reproductive success, and when they persistently fail to conform to group norms. Social ostracism is associated with negative physical and psychological health, including distress and death. Individuals may behave prosocially to avoid or reduce ostracism or to regain group inclusion following ostracism.

## Socialization

Irena Petak  
Zagreb, Croatia

## Definition

Socialization is the process of acquiring social rules and adopting behavioral patterns applicable to an individual's social environment. Through the process, an animal develops its own species identity and personality. An animal needs to be socialized with members of its own species, but members of other species with which individual interacts influence its social development as well. Socialization starts in young animals, and it is the most effective in sensitive period before they reach maturity, but it is a lifelong process.

## Introduction

In the course of evolution, sociality has emerged as an advantage for certain species. Appearance of social life required certain behaviors by which functioning of a social group can be achieved. By living in diverse ecological conditions, inhabiting diverse ecological niches, certain animal species have developed different levels of sociality or different kinds of social organization, and therefore their processes of socialization may also differ. Hence, social animals form more or less

stable social groups where even several generations may live together, and cooperation and competition over resources happen over the course of time. Socialization is described even in social insects, such as ants and bees (Scott and Fuller 1965; Rittschof et al. 2015), but the process of socialization has been mostly researched in mammals and birds.

## Primary and Secondary Socialization

Social skills, crucial for surviving and reproduction, are something that animals acquire through learning over their whole life. However, the most important aspects of social life have to be obtained during sensitive periods in very young animals, when appropriate species-specific behaviors for adult animals develop (Murray et al. 2014). Firstly, primary socialization occurs, where emotional attachment is formed to members of a parent species or surrogates. This process takes place in very young animals, no matter if the animal is rewarded, punished, or treated indifferently by an individual or object of socialization. It ends with the development of fear response (Blackwell 2010; Scott and Fuller 1965). Primary socialization is followed by secondary socialization, when an individual is entering in new parts of social life and may engage in interactions with littermates or peers (Blackwell 2010; Scott 1962).

### Primary Socialization and Mother's Influence

The period of early socialization starts when the nervous system in a young animal is developed enough to receive information from the environment, i.e., when hearing, vision, and temperature regulation are stable. Consequently, young animals become sufficiently mobile and start to develop social relationships with other animals in their environment. The developmental timeframe for socialization in mammals and birds depends on how developed they are in the moment of birth or hatching, i.e., if they are precocial (able to walk briefly after birth or hatching) or altricial (born or hatched in immature state). Since precocial animals are more developed when they are born or hatched, their socialization may

start immediately, while in altricial species it is delayed since they develop more slowly. Therefore, precocial species tend to have earlier and shorter periods of socialization (Scott and Fuller 1965). No matter the developmental differences, altricial and precocial species are successful in maintaining complex social life (Scheiber et al. 2017).

Additionally, ungulate species, which are all precocial, are considered as the “hiders” and the “followers” with regard to the type of mother-infant relationship occurring after the postpartum period. In “hiders,” the mother leaves the infant hidden and joins her herd. She comes to the infant only for nursing two or three times per day, and therefore socialization in “hiders” may start when they join the mother’s herd. On the other hand, in “followers” mother and infant join her herd together, so socialization may start immediately (Lent 1974).

Dogs and cats, however, are examples of altricial species, and their socialization starts after the neonatal and transitional period – a period where neonatal behaviors change to be more like in adult animals (Scott and Fuller 1965). The socialization window in dogs (*Canis familiaris*) is between 19 days and 12 weeks and in cats (*Felis catus*) is between 3 and 9 weeks of age (Case 2010; Landsberg et al. 2003).

The connection that a young animal has with its mother can be especially important for the early socialization period. These relationship will often have lifelong influence because young animal learns mother’s social behavior (e.g., mares, *Equus caballus*, influence their foals’ behavior toward humans (Henry et al. 2005)) but also through epigenetics where the level of maternal care has consequences for a development of their offspring stress susceptibility (Champagne and Curley 2009) and cognitive development (Liu et al. 2000), which are both important for maintaining social lives. Mothers are often the first socialization partner in many species (e.g., sheep, *Ovis aries*, and goats, *Capra hircus* (Collias 1956); bottlenose dolphins, *Tursiops truncatus* (Mackey et al. 2014)). Therefore, in social mammals, socialization of the young is an important component of maternal care, and it is a

basis for normal behavioral development (Mills 2010; Scott and Fuller 1965).

Furthermore, a mother's social life can be crucial for the socialization pattern of their offspring in some species. For example, mother chimpanzees (*Pan troglodytes*) with female offspring tend to reduce association with others. However, lactating chimpanzee females remain together to enhance socialization opportunities for their immature male offspring, and they prefer to associate with other females who have similarly aged offspring. Mothers with sons spent significantly more time in groups containing males during the first 6 months, providing their young with important observational learning experiences and social exposure early in life to ensure sex-appropriate social development (Foerster et al. 2015; Murray et al. 2014). However, since male chimpanzees pose a danger for the offspring, mothers tend to keep their offspring closer when males are present in the group, and they are more attentive (Otalí and Gilchrist 2006).

A mother serves as a secure base for an infant when it starts to explore the environment and interact with other group members. This can be observed in primates, such as blue monkeys (*Cercopithecus mitis stuhlmanni*), even in society where the rate of in-group aggression is low, and large juvenile females regularly help with care of infants (Förster and Cords 2005).

For young wolves (*Canis lupus*), the socialization period starts when they are 20–24 days old, which corresponds to when they start to explore the entrance to the den. As they leave the den, they begin to socialize with other pack members. In this sensitive period of socialization, they are rather nonselective of which pack member they approach (Packard 2003).

### Secondary Socialization and Importance of Play Behavior

An important part of the ontogeny of social mammals is the establishment of social relationships with other members of their species, which is achieved by social play with littermates or peers. For species living in complex social systems with an extended juvenile period, play is an important factor in the young animal's socialization. In rats

(*Rattus norvegicus*), social play modifies the development of the brain, especially the prefrontal cortex, and this improves their social skills. Consequently, rats that play as juveniles are more socially competent as adults (Pellis et al. 2010, 2014).

By playing, young animals practice motor skills needed for success later in life, such as capturing prey and species-specific courtship behavior. Play can also allow individuals to evaluate their competence against peers and create social affiliations that can extend later in life. It is in this phase that species identity is formed because it is not strictly genetically determined (Blackwell 2010). In bottlenose dolphins, the first play partners for young animals are their mothers, and then later, other calves become the most common social play partner. The play with peers allows a young animal to develop its social skills more efficiently, as well as to adapt to novel situations, enhance motor skills, train for mature social interactions, and advance its cognitive abilities (Mackey et al. 2014).

In elephants (*Loxodonta* sp.), early socialization is with the mother, as well as allomothers (juvenile and adolescent females from the herd that assist in care and protection of calves). In adolescence, young male animals have a second phase of socialization when they leave the maternal herd and join older all-male groups. During this second phase, it is thought that the presence of older males facilitates normal social development of young males by reducing their aggressive behavior tendencies (Bradshaw et al. 2005). Namely, adolescent male African elephants need to be with older bulls to gain social and ecological knowledge from more experienced individuals, and that should enable them to become functional social members without posing a competitive threat. It may be considered that mature males are important in the stability of bull society, and their role may be similar to that of the matriarchs in the breeding herds (Evans and Harris 2008).

In some highly social birds, young animals can be left in crèches with siblings and offspring of other adults, as, for example, in spectacled parrotlet (*Forpus conspicillatus*) and pinyon jays

(*Gymnorhinus cyanocephalus*). Here young animals have the possibility to play, to learn to recognize other individuals, and to form social bonds (Wanker et al. 1996; Clayton and Emery 2007). Moreover, this social grouping allows animals to learn to recognize each other, since individual vocalizations contain “signatures” that are unique for certain individuals, just as facial recognition is for other species (Clayton and Emery 2007). Bird species with delayed reproduction and persistent association of juveniles and adults often have more complex social play (Diamond and Bond 2003).

### Socialization in Wild Species and Anthropogenic Influences

Socialization is accomplished over time by diverse social, biological, and maturational factors that an animal is exposed to. In nature, socialization occurs spontaneously. However, problems may happen with human involvement on several levels. In experimental settings, complete isolation of young animals results in socially incompetent individuals, with severe behavioral problems (Scott and Fuller 1965). Similarly, in many wild animal shelters, abandoned young animals are not raised by their parents in their natural social environment, but rather by humans. Furthermore, young animals in shelters may be exposed to other animal species, which may lead to unwanted socialization. Indeed, nature and nurture play a very important role in a young animal development, so obtaining social characteristics of another species, or becoming tolerant of their presence in the case of predators, may be a disadvantage in a natural environment. This can be seen in both birds and mammals. Consequently, it may render them incapable of life in nature.

Birdsong is a complex vocal behavior learned during early life, and in many species, young male songbirds have to learn their song from their fathers because it is species-specific. Male white-crowned sparrows (*Zonotrichia leucophrys*), for example, need to be exposed to the song during a critical period of 10–50 days of age for normal song development to occur (Marler 1970). If

young birds are exposed to another species or raised by humans in animal shelters, sometimes they learn the wrong species’ song, especially if it is a related species. Since song is important for territory protection and attraction of mates, this failure in socialization may cause vital problems in their later life (Spencer et al. 2007).

The lack of proper socialization may also represent a problem when birds from breeding programs need to be reintroduced into the wild. In the research conducted by Snyder et al. (1994), thick-billed parrots (*Rhynchopsitta pachyrhyncha*) were repopulated in Arizona, where they went extinct some time ago. Unfortunately, hand-reared birds from breeding programs had poor survival rates because of deficits in foraging and socialization, and their population was quickly devastated by predators. However, parent-reared captive bred birds were more successful upon release into the wild than hand-reared birds. The best survival rates had wild-caught adults that were translocated to Arizona.

The reintroduction of carnivores raised in captivity by humans has also been equally unsuccessful in some contexts. Captive-born carnivores were particularly susceptible to starvation, unsuccessful with predator/competitor avoidance, and more prone to disease in reintroduction programs (Jule et al. 2008). Similar to the parrots described above, wild-caught carnivores were significantly more likely to survive than captive-born carnivores.

For large herbivores that live in matriarchal societies, proper socialization is crucial for survival. Indeed, African elephant (*Loxodonta* sp.) families and social structure suffer from growing human populations that destroy their environment. Unfortunately, by current conservation methods, elephant social systems are not preserved since there are not enough older herd members in shelters. Additionally, in human selection of individuals that do not take in count their heritable sociability, and in the absence of normal socialization, behavioral problems may rise under these adverse conditions. Therefore, it becomes important to assess the kinds of social behavior that should be chosen through conservation programs, if we wish to maintain normal social

patterns in African elephant society (Bradshaw et al. 2005).

In human-made environments, with additional effort, successful rehabilitation and socialization of adult animals can sometimes be achieved, even when animals were traumatized as young. Indeed, chimpanzees (*Pan troglodytes*) used for entertainment and as pets were effectively socialized and mixed in a primate rescue and rehabilitation center (Llorente et al. 2015). Although these animals can be partially rehabilitated, they are typically not reintroduced to nature because their social skills will never be fully normalized.

Socialization is also important in the context of taming wild animals. Indeed, animals that become accustomed to humans, especially if they are hand reared, often display affiliative behaviors toward people. This can be a problem if they are to be released into the wild since they may seek human contact, which can be dangerous for both the animals and humans. However, the ability of individual animals to socialize with people may also be the basis for animal domestication as an evolutionary process (Blackwell 2010).

## How Domestication Influences Socialization

Domestication for life with humans places new requirements on a species. Most notable is that they need to be socialized not only with their own species but also with humans and other domestic animals they may live with. In domestic environments, young from different animal species socialize from early age on, playing together or even being raised by mothers from a different species. Here, socialization is very powerful because it can cause a domestic animal to alter its prey and mate selection (Landsberg et al. 2003; Blackwell 2010).

One distinguished characteristic is that in domesticated animals, the socialization period is prolonged. This was shown in the so-called silver fox (*Vulpes fulvus*) experiment, conducted by Belyaev and his colleagues (1985). They had two populations of foxes, one selected for tameness (experimental group), whereas the other

group did not undergo any selection (control group). The socialization period of pups started when they are 20–25 days old. In unselected foxes (control group), the main period for the formation of primary social bonds was between 30 and 35 days, when maximum exploration in a novel situation was shown. Furthermore, the period between 40 and 45 days was the upper boundary of primary socialization, when further exploration was prevented because pups started to show fear in response to novel stimuli. However, for the pups from the population of experimentally domesticated foxes (experimental group), the sensitive period of socialization was prolonged to over 60–65 days of age. Hence, in the selected foxes, the window of social bonding started 1–2 days earlier and ended about a month later relative to the unselected foxes.

During this extended socialization period, domestic animals should develop a sense of belonging to its own species – this is achieved through the relationship with its mother, siblings, and other members of social group (e.g., flock or herd). Adequate socialization should result in an appropriately functioning adult animal capable of interacting in a species-typical and predictable way with other members of its own species. In addition, every domestic animal needs to have a lot of pleasant experiences with humans, such as with owners, caregivers or handlers, veterinarians, but also other people that they may live with in the future. In a human environment, a barn or an apartment, an animal should feel calm and relaxed, which will ensure that every procedure that involves an animal is safe for the animal itself as well for humans (Broom and Fraser 2007).

In pigs (*Sus scrofa*), before farrowing, the sow seeks isolation from her social group to build a nest. The piglets stay there for about 1 or 2 weeks and then join their mother's social group. However, under farm conditions, piglets are often removed from the mother immediately, and therefore reunion of piglets happens later, once piglets are weaned, and consequently fights between unfamiliar piglets occur (Broom and Fraser 2007). Thus, Petersen et al. (1989) emphasized the importance of early socialization for piglets since their integration into social groups was more

peaceful when they had the opportunity to make early contact with piglets from other litters of the same age (2–7 weeks old). Therefore, properly timed socialization can be a major factor for the reduction of aggression between farm animals.

Dogs and cats are the most popular pet animals today. Unfortunately, these pets are sometimes raised in isolation from the outside world before they get vaccinated against most common infectious diseases (preventive healthcare), and because of this incomplete socialization, many behavioral problems arise (Landsberg et al. 2003). For both species, it is essential that the first phase of socialization is spent with their mothers and siblings to acquire basic social skills. After the puppy or the kitten comes to the home of the new owner, at the age of 8–10 weeks, they should continue socialization by getting to know others of their own species (different individuals, different breeds), humans, and other animals with whom they will spend the rest of their lives (Case 2010).

Dogs (*Canis familiaris*) are more closely attached to people than other animal species, and they develop a relationship, which in many ways, is similar to the human parent-child relationship. It is interesting that for dogs a human owner can represent a secure base, similar to the role mothers serve in other species. This is considered to be a consequence of the domestication process, where dogs retain their childlike qualities throughout their lives (Mariti et al. 2013).

Domestic cats (*Felis catus*) become more social in other cats' presence through the process of domestication. While most species of wild cats have only a brief period during kittenhood when they tolerate the presence of other individuals before they become more solitary adults, domesticated cats readily coexist with other cats, with animals of other species, and with humans (Thompson 2010). This exposure to other species during socialization may reduce predatory behaviors, such as seen by domestic cats not preying upon rats with which they have shared a household (Landsberg et al. 2003).

In domestic environment, it may happen that instead of mother, humans take care of a young animal, or even an animal of some other species may become a surrogate mother. If an animal is not nurtured by its mother or another female

of the same species, it is particularly important that in addition to the relationship with the human, it has pleasant experiences with members of its own species. In those animals that do not have such opportunities, social behavior may be directed more broadly toward humans and other species. This may raise some behavioral problems, e.g., the animal may have no interest for socializing with members of its own species or may court females of “wrong” species or develop an inappropriate relationship with members of the species that raised it (Broom and Fraser 2007; Scott 1962).

However, in our homes not only domesticated animal species are kept as companion animals but also wild animals (monkeys, squirrels, parrots, reptiles, insects, etc.). For taming the wild animal, extensive early socialization is extremely important. This socialization should be structured with respect to the species natural behavior and ecology. For example, in nature, psittacine birds live in complex social groups called flocks. Therefore, in human homes, if the bird is not provided with appropriate socialization opportunities, behavioral problems may occur. For example, when the birds reach sexual maturity, they may try to form a sexual bond with a human caregiver. Undesirable sexual behaviors comprise attempts to preen, allofeed (regurgitate), and copulate with the person. Further problematic behaviors that have been observed are masturbation, aggressive attempts to drive away other members of the family, and defense of the cage as a nesting site. Additionally, abnormal behaviors that indicate stress or anxiety can arise, including feather picking, self-mutilation, screaming, aggression, and biting, as well as phobias (Seibert 2006).

Finally, proper socialization to humans should be an important part of work with laboratory animals, since that may enable secure procedures for the animals, as well as humans. Proper socialization can also reduce stress in laboratory animals, which will result in more reliable experimental data being obtained, as was shown with rabbits (*Oryctolagus cuniculus*) (Swennes et al. 2011). Equally, unwanted behaviors can be prevented as in the example of later socialization of rhesus monkeys (*Macaca mulatta*) (Weed et al. 2003).

## Conclusion

During the process of socialization, an individual builds its relationship with its mother and learns to behave in a socially acceptable way among the members of its own species and those of other species when necessary. At a young age, animals start to learn the recognition of family members and allies, as well as individuals who may pose a threat for its existence. Experiences gathered during the early stages of life appear to be more important than those occurring later in life, indicating a sensitive period for socialization, and acquisition of appropriate social behavior in adulthood.

Later socialization or resocialization is at times possible and can be achieved through learning processes. However, if the animal was not previously socialized (i.e., kept in isolation or if subjected to some social trauma), this learning may be more difficult. Traumatized animals will be more difficult to socialize, and in some cases, at least for companion or zoo animals, medication may be needed to enable the process.

## Sociobiology

John Alcock

School of Life Sciences, Arizona State University, Tempe, AZ, USA

## Introduction

Sociobiology was founded by E.O. Wilson (1975) in a massive book of the same title. However what Wilson really did was to give a name to a field that was already being developed in evolutionary biology, the study of the adaptive

value of social behavior. His contribution was important because he examined all aspects of social behavior then known with separate chapters on the behavior of birds, mammals, insects, and the like that were known in 1975 to live in groups and behave socially and whose behavior had been demonstrated to promote the reproductive or genetic success of individuals. The field would have probably remained uncontroversial were it not for the strong negative response of opponents led by some of Wilson's own colleagues at Harvard, namely, Stephen Jay Gould and Richard Lewontin. These opponents, the self-named Science for the People, produced strongly worded attacks on the book *Sociobiology* and its author claiming that sociobiology incorporated outdated and incorrect approaches to social behavior (Allen et al. 1975, 1976). The vehemence of the opposition to an evolutionary analysis of social behavior was encapsulated in the desire with which the opponents sought to link Wilson with the Nazis, eugenics, and other discredited persons and activities despite the academic nature of his synthesis which barely touched upon human behavior, the focus of the opposition. This attack led to physical assaults on Wilson including the pouring of cold water on his head by a member of the Science for the People at a conference in which Wilson attempted to speak.

Among the objections raised by the opponents of sociobiology, who include Michael Rose (1998), is that he wrote that we rarely if ever wish to raise our genetic success when behaving socially. This is true enough but our proximate (immediate) desires get us to behave in ways that influence the transmission of our genes to subsequent generations. In other words, our wishes and emotions that cause us to behave in certain ways have evolutionary (long-term) significance. And proximate physiological systems therefore can evolve as certain proximate mechanisms lead to greater adaptive results, i.e., gene propagation, than others with the logical conclusion that those social desires that are associated with superior reproductive or genetic success will become more and more common over time in populations of social species.

Likewise, the objections that sociobiologists, like Wilson, are genetic determinists who believe in a one-to-one relationship between genes and behaviors, a point repeatedly raised by Stephen Jay Gould (1976, 1996), are misguided. The proximate genetic aspects of development of a person are not the essence of sociobiology which instead deals primarily with the possible adaptive functions of social behavior. Notice that the previous sentence states "possible adaptive functions" since the goal of sociobiology is to test hypotheses on the genetic value of possible adaptations associated with social behavior. As T.H. Huxley (1910), the great defender of Darwinian theory, wrote, "There is a wonderful truth in [the] saying [that] next to being right in this world, the best of all things is to be clearly and definitely wrong, because you will come out somewhere."

This approach tells us that another chief criticism of sociobiology, particularly of humans, is without merit, namely, that evolutionary studies of social behavior contribute to social injustice and inequality which arise because of attempts to justify certain patterns of social behavior, a criticism raised by Science for the People (Allen et al. 1975, 1976). In reality, tests of hypotheses on the adaptive value of social behavior are designed to explain why we and other social organisms do what we do, not to justify that activity (Alcock 2001; Rubenstein and Alcock 2013), a point that is obvious when the social creature under examination is an insect rather than a human. No one argues that the stings of honey bees are justified by an analysis of the adaptive value of stinging by worker bees. The goal instead is to explain why workers sting and how this social behavior (colony members detect stinging by others and join the stingers) advances the success of the genes of the worker.

### **The Selfish Gene**

Another extremely important book, *The Selfish Gene*, was written by Richard Dawkins (1976) about the same time as *Sociobiology*. In it Dawkins explained why the arguments

of adaptationists (persons who rely on the theory of differential genetic success) were so useful for sociobiologists and behavioral ecologists, both of whom use Darwinian natural selection as the basis for their adaptationist hypotheses. Although Darwin was clueless about genetics, because Mendel's work was unknown to him and other biologists prior to the early 1900s, his insights in *On the Origin of Species* (Darwin 1859) in which he presented the theory of natural selection provide the foundation for all modern evolutionary behavioral work, a point that Dawkins explained clearly – despite the arguments that others raised against the book, most of which deal with the title of the book. Dawkins spends the bulk of the introduction to the third edition in a defense of this title, *The Selfish Gene*, which some people insisted upon interpreting as meaning that Dawkins was saying that genes were selfish in a proximate sense rather than selfish in an evolutionary sense. As Dawkins notes, genes can cooperate proximately (developmentally) if the result of their cooperation is the promulgation of those genes against alternate forms that differ from the more successful genes. In his book, Dawkins showed how the fundamentally Darwinian evolutionary selfishness of genes was the product of natural selection with genes selected (becoming more common) on the basis of their copying success. He explained that since only genes survive from generation to generation, genetic success was more important than that of the individual or species or group in which the genes reside. Awareness of the gene encourages us to understand why genes can cooperate in the building of cooperative individuals whose help given to others results in additional copies of the genes in question. In the course of *The Selfish Gene*, Dawkins highlights the work of George C. Williams and William D. Hamilton, both of whom used the ideas of Charles Darwin to set the stage for the focus on the gene, showing how individual survival machines worked to pass on their genes to future generations, and thereby determined which genes would live on and which would die out as a result of Darwinian selection.

## George C. Williams and the Essence of Sociobiology

G.C. Williams (1966) was the most important of these persons when it comes to sociobiology. His book, *Adaptation and Natural Selection*, made the case for individual selection (via the gene) as being far more significant than group- or species-level selection. He did so by contrasting the power of individual selection against that of group selection. He posed a thought question by asking his readers to consider what would happen if natural selection occurred and individuals sacrificed their reproductive success to benefit the group, an extremely widespread explanation for social behavior at the time, a point of view championed by V.C. Wynne-Edwards (1962). For example, territorial behavior was widely thought to evolve if non-territorial individuals promoted the survival of the species either because the non-territorial types were inferior or because breeding by these individuals would threaten the survival of the group through over-population. However, as Williams noted such a situation would be vulnerable to an invasion by genes that caused their owners to refuse to be non-territorial sacrificing themselves for the benefit of the group. If only territorial individuals passed on their genes to the next generation, in time there would be no non-territorial individuals possessing the genes for self-sacrificing non-territoriality. In other words, if one observed both territorial and non-territorial members of a given species, one had to think of a way in which the non-territorial individuals experienced genetic success, not a way in which the group benefited from the behavior of the non-territorial types. The hypothesis that non-territorial individuals sacrificed for the territorial members was a non-starter.

In every situation in which group selection à la Wynne-Edwards was used to promote the idea that individuals gave up reproductive chances to help others of their species to reproduce, Williams's explanation focused on the benefits to individuals to do what they did in order to secure genetic success. So, for example, if birds flew in large flocks to get information about the density of

competitors in an area, the group selectionist explanation was that some birds used this information to reproduce less in order to help the species to avoid over-population. Williams proposed that some birds used this information to avoid trying to reproduce at times and places that would almost certainly have resulted in reproductive failure by the birds in question. This hypothesis had the virtue of not arguing that some birds would give up reproduction (and thus genetic success) to assist others, a recipe for the disappearance of those genes that induced some birds to sacrifice for others, whereas if by giving up reproduction temporarily, those individuals had more surviving offspring in their lifetime than they would otherwise, the genes for using density information to regulate reproduction could spread through a population.

### **Male Lion Social Behavior: Coalitions of Unrelated Individuals**

Male lions often form groups that seek to take prides of females from other males, a social behavior that can be understood as way in which individual lions seek to pass on their genes. Although these groups are sometimes composed of relatives, a fact that makes groups of this sort understandable in a Hamiltonian sense (see below), sometimes the groups are made up of unrelated males. The question is how does one account for groups of non-relatives in Williams's terms? As it turns out, cooperation of the sort seen in lions can evolve by natural selection if it generates increased reproductive success for the cooperators even if some males reproduce less than others. Thus, if several unrelated males succeed in securing a pride, their reproductive success merely has to be greater than it would otherwise in order to support a hypothesis that explains their social behavior in terms of individual genetic success as opposed to group benefit selection. (Again there are logical reasons in favor of the individual selection hypothesis that makes this explanation worth considering, whereas the group selection alternative is untenable if the hypothesis requires that unrelated individuals

sacrifice their reproduction to benefit the group or species.) All the unrelated males stand to pass on some of their genes if through their cooperativeness they defeat another group of males, ousting them from a pride of adult females. Thus the individual selection hypothesis not only does not require that some male lions sacrifice their reproductive chances to help other males in the coalition, this explanation also generates predictions that can be checked, thereby testing the individual selection hypothesis. We can predict that when non-relatives join together, they will do so to take a pride from a smaller coalition of males. Moreover, those non-relatives that have no or little genetic success (i.e., if other males do most or all of the mating) and then those unrelated males that cooperate in securing a pride but have little reproductive success should weigh less than the dominant lions in the group. Males that weigh less than average are expected to be handicapped in the effort to secure a pride that will generally be held by groups of males favoring those that join others in defeating groups of rivals that control a pride. The point here is that the opportunity for some reproductive success (i.e., genetic success) is better than none. Single males that fail to secure a pride when up against groups are expected to have no reproductive success at all.

### **Male Lion Social Behavior: Coalitions of Related Individuals**

Male lions often form groups composed of relatives, and in this case there is yet another hypothesis that looks to the genes of the males in the coalition for an explanation for their social behavior. Relatives (brothers, half-brothers, and cousins) share genes in common as a result of having a shared ancestor. The reason why W.D. Hamilton (1964) is viewed as an admired and influential theorist in sociobiology has to do with his focus on shared genes that led him to point out that although reproduction enables an individual to transmit genes directly to the next generation, helping relatives reproduce can achieve the same end indirectly. Therefore if a

coalition of male lions is composed of relatives, even those individuals that have little or no genetic success via reproduction can pass on their genes indirectly – if they help their relatives reproduce successfully. Therefore one can predict that in coalitions of related males, reproduction by some individuals will be helped by the non-reproductive lions (primarily in the takeover of prides from other groups of males). In other words, some indirect genetic success is better than none, and no genetic success would be the typical fate of those solitary individuals that did not help related males to acquire prides of females.

After Hamilton's argument was published, it has become extremely important in accounting for many cases of social behavior in which the key prediction is that groups of cooperators will be composed of relatives (primarily close relatives with a high proportion of shared genes).

### **Acceptance of Genic vs Group Benefit Selection**

It is safe to say that the vast majority of sociobiologists and behavioral ecologists have accepted the views of Williams and Hamilton and rarely if ever bother to test illogical group selectionist hypotheses about the benefits of social behavior to groups or species as a whole. There are however several researchers who continue to try to argue that group selection is important to the evolutionary process rather than direct gene (personal reproduction) or indirect gene (help given relatives) selection. Among these theorists is E.O. Wilson who has abandoned his view that the vast majority of cases of social behavior can be explained in terms of direct or indirect gene transmission in favor of the position that group selection accounts for much of the social behavior of organisms. He appears to have been persuaded by David Sloan Wilson (not a relative of E.O. Wilson), a long-time advocate for group-level selection, to change his support for sociobiology (Wilson and Wilson 2007).

However, none of these advocates for group selection has had much success in converting

others to their viewpoint. For most sociobiologists the social behavior of individuals is to be investigated using the principles of Williams or Hamilton. This point can be made by showing how research on the adaptive value of animal social behavior has either examined the reproductive importance of the behavior to social individuals (with each individual produced by personal reproduction carrying half the genes of the reproducer) or how individuals help their relatives reproduce (and thereby secure genetic success in proportion to the relatedness of the individual that they help) as illustrated by male lion social behavior.

So, for example, both males and females form social units in many species. These were once interpreted as primarily cooperative, and of course there is much that is cooperative about male-female bonds. However, the aspect of pairing that reflects Williams's approach most clearly is research into conflicts between males and females, research by sociobiologists and behavioral ecologists (many sociobiologists prefer to be called behavioral ecologists thanks to the unhappy start of the field of sociobiology) that has exploded in the years since the publication of Williams's book. These conflicts can and do occur as individuals of both sexes try to leave the offspring in the care of the other member of the pair. Males are especially likely to abandon their progeny in many species in order to inseminate as many females as possible since male reproductive success is often a function of the number of mates a male has whereas female reproductive success is more often linked to the quality of the mate, rather than the number of sexual partners acquired. The rarity of monogamy by males speaks to this argument and to the value of Williams's position.

### **More Cases of the Utility of Individual Selection, Including More Examples of Sexual Conflict**

Likewise the existence of forced copulation in many animals including humans is clearly a function of the benefits to the male of forced

**Sociobiology, Fig. 1** A group of male bees (*Amegilla dawsoni*) surround a recently emerged virgin female with each male attempting to be the one that inseminates the female, an activity that endangers the female

copulation and the costs to the female that is subjected to forced copulation. For example, in observations of mating in Dawson's burrowing bee, *Amegilla dawsoni*, bundles of tussling males often form around a freshly emerged female, a receptive virgin female (Fig. 1). These mobs of males assemble because of the benefits to males in being the one male to copulate with a female but occasionally result in the decapitation of the female, a clear case of male-female conflict in this species caused by the attempt to inseminate the female.

In fact the resistance to mating exhibited by females of many species reduces the reproductive success of the rejected males and as such constitutes sexual conflict that arises because females are not equally receptive to all males in most cases. In addition, in species in which females eat males that approach them, we have further evidence of sexual conflict because it is rarely advantageous for a male animal to be consumed by a potential partner.

In insects females commonly exhibit an immune response that enables the females to avoid sexually transmitted diseases but that reduces the reproductive success of males if it kills some of their sperm. Evidence that such a response occurs in a cricket has been assembled by Fedorka and Zuk (2005) along with the finding that males attempt to suppress the immune response of females, further

evidence that sexual conflicts are widespread in insects.

The increase in attention given to cases of sexual conflict between potential members of social units is matched by an increase in research into how males insure that their inseminated sperm are actually used to fertilize the eggs of females. In some instances, females accept sperm from more than one sexual partner, and in these cases, males have been shown to behave in ways that increase the odds that their sperm are used to fertilize the eggs of their mates, an ability that was not explored prior to Williams's book, not even by Darwin as shown by Eberhard (2009). One such tactic is mate guarding by males designed to prevent multiple mating by a female partner that has accepted sperm from the mate-guarding male (Fig. 2). Sperm competition of this sort is now known to occur widely in the animal kingdom as is multiple mating (polyandry) by females, which promotes the evolution of sperm competition (a potential form of sexual conflict between the sexes).

Williams's argument also receives support from studies of many other elements of social behavior such as parental care of parasites by birds. Although some birds take care of parasitic species, an apparently maladaptive behavior, when work is done on the genetic benefits and genetic costs of doing so, one usually finds that the costs outweigh the benefits of ceasing to feed the parasitic offspring or abandoning the nest. These costs to reproductive success include the risk that a parasitic bird(s) might return to the nest of its host to destroy the eggs in the nest of the host (Soler et al. 1995).

## Acceptance of Indirect Selection

Although Williams caused most sociobiologists and behavioral ecologists to examine hypotheses on the reproductive value of social behaviors, often it is clear that the behavior is altruistic, that is, the behavior helps others at the cost of reducing the reproductive output of the helper. Under these conditions, an alternative solution to this puzzle is required that does not involve group benefits of some sort. Here Hamilton's approach has been

**Sociobiology, Fig. 2** A male damselfly (*Calopteryx maculata*) with the green abdomen guarding an egg-laying female using materials in his territory as an oviposition site

often used by showing the altruist is related to the individual he or she helps, thereby increasing the representation of the altruist's genes in the next generation. As documented already, this approach makes sense of the behavior of male lions, some of which form coalitions of relatives that are large enough to overcome the coalitions of other males that monopolize the sexual output of the pride of lionesses that they control. In order to use this approach however, one has to show that the loss of reproduction by the altruistic helper is exceeded by the gain in its genetic success as measured by the genes passed on as a result of the help. So, for example, an altruist that helps a brother produce two more offspring than he would otherwise have gains two times a half or 1 genetic unit since brothers are related by a half to the altruist and to their own offspring. If the cost of its helpful behavior is the loss of two offspring produced personally by the altruist, then the loss is two times a half or 1 genetic unit as well. In other words, in this case both altruism and personal reproduction are equally effective in passing on the genes of both types of behavior, indirectly and directly.

### Cases Demonstrating the Utility of Indirect Selection

Hamilton's approach has been widely adopted for lions and certain other mammals, those birds that nest in groups in which some individuals appear

to help others reproduce, and social insects where altruism by workers is widespread. A mammal in which helping by relatives has evolved is the naked mole-rat (Sherman et al. 1991). This odd hairless mammal lives in underground colonies in Africa with large numbers of altruistic worker mole-rats that help a single reproducing "queen" and a small number of males that sometimes pass on their genes by mating with the female in charge of the colony. The helpful altruists that dig tunnels through the soil and secure tuberous food for the queen and kings are all progeny of the reproductive members of the colony as expected by Hamiltonian researchers.

Cooperative breeding in birds is fairly common, especially in Australia where the phenomenon occurs often, particularly in honeyeaters (Fig. 3) and fairy wrens. The general rule is that certain of the offspring of 1 year help rear the progeny of the next year although in some cases of cooperative breeding in birds, some of the helpers are related to their parents and others are not. In those species in which some helpers are unrelated to the youngsters that they help feed and protect, the demonstration that these helpers are more likely to reproduce in future years than non-helpers supports the prediction that helpers secure future reproductive success that compensates them for their reduced reproduction during the time that they behave altruistically. The non-relatives not only go on to breed more often than non-helpers, they also help less than the related birds. In instances in which helpers are

**Sociobiology, Fig. 3** A yellow-fronted honeyeater, one of many cooperative breeding birds in Australia

relatives that behave altruistically to their parents and to their siblings, the loss of reproductive output in one season is offset by the increase in siblings whose 0.5 relatedness to the altruist compensates him or her for the loss in that year.

In any event, the prediction that follows from the Hamiltonian approach is that helpers that are related to the parents that they help must increase the number of siblings that are generated in the nest. This outcome is generally observed in cases in which the prediction has been examined. Thus in the yellow-fronted miner (an Australian honeyeater), it has been shown that nests with helpers are more productive than nests without helpers. The same applies to the noisy miner with the further findings that males are more likely to help than females (which are able to reproduce sooner than males) and the effort expended by related individuals is greater than that engaged in by non-relatives (Barati et al. 2018). In bell miners, males are also more likely to help than females, and furthermore, helper males are typically fathered by parent males that mate with a single female so that helpers are more closely related to the siblings they provision and protect than they would be if their fathers mated with several females (which would mean that the relatedness of offspring was diluted by the different genes present in the eggs of those females). These results support predictions that a Hamiltonian would make and thus provide support for the hypothesis that relatedness is the cause of much

helping at the nest in birds. In the long-tailed tits of Europe, altruistic helpers focus on nestling relatives over 90% of the time showing the kind of preference that has been predicted by indirect selection proponents.

## Insect Sociality and Altruism

Thus in vertebrate mammals and birds, Hamilton's ideas can supply a solution for the puzzle caused by help given to some individuals by others. However, most of the altruistic mammals and birds go on to reproduce. Although in some insects helpers have the capacity to reproduce, in others some individuals spend their entire lives working for others and indeed have rudimentary reproductive organs so that they could not reproduce even if they tried to do so. Among the insects, altruists are especially well represented in the bees, wasps, and ants.

Paper wasp workers have the ability to lay eggs in the nest that they are caring for (and thereby secure direct personal reproduction). These *Polistes* wasps include the northern paper wasp, a common species in the eastern United States where porches are often used as nest site. Frequently sisters that can sting and sometimes drive away nest raiders such as birds and raccoons join forces to start a nest (Fig. 4) and thereby double the protective services available at a nest, which as it grows in size becomes a nursery for smaller female wasps that help protect and feed their siblings, many of which will emerge from the cells of the nest as worker females as well. Should the original founder disappear through death or predation, helpers can transform themselves into reproducers and secure the benefits of direct reproduction after having derived the genetic gains that come from assisting a mother queen wasp in reproducing future queens.

Eventually the nest is used to produce a group of reproductively active males that seek out adult females and inseminate them; these females spend the winter in a safe place, and if all goes well, they become the foundress females at nests that contain a new generation the following year, an annual cycle that is covered by Evans and Eberhard

**Sociobiology, Fig. 4** (a) A pair of *Polistes fuscatus* paper wasps that cooperate in the building of the nest and in the protection of larvae. These individuals are probably sisters with one female laying most or all of the eggs in the nest and the other helping her close relative. The

photograph was taken in early June. (b) By mid-August many worker females have emerged from the same nest but now larger that was founded by the two females much earlier in the year

(1970). If a worker female lays an egg in one of the brood cells of the nest, the reproductive female or a fellow worker will generally consume that egg, preventing the worker from reproducing, which it can do but is usually unable to do because of removal of its eggs from the nest. Indeed, the greater the genetic difference between a queen's sons and the sons of workers, the more likely the eggs of workers are to be destroyed by fellow nestmates in the wasps, bees, and ants. In other words, when worker offspring are less closely related to other workers than to the offspring of the reproductive individuals, the more likely their eggs are to be eaten by other workers and queens (Wenseleers and Ratnieks 2006).

More importantly, worker paper wasps are all female, instead of mostly male as they are in honeyeaters and other birds. One assumes that the prevalence of female workers in wasps, ants, and bees stems from the ability of females in these groups to sting, which can deter predators from assaulting the nest with its edible larvae.

By far the most well studied of Hymenoptera are the honey bees, *Apis mellifera*, whose queens lay thousands of eggs destined to become daughter workers that help the queen manage the colony, feed the brood, and sacrifice themselves in stinging vertebrates that would plunder the hives if not checked. (The worker bees commit suicide when stinging animals with flexible skin in which their stingers catch, pulling out the still functional

stinger and the internal organs of the worker). Since honey bees are the offspring of the queen and are related to any future queens, they can engage in helping behavior if their actions benefit the queen or a future queen (Seeley 1995). Half of the hive (largely female workers) will stay with a reproductive daughter of the queen when the queen leaves in a swarm to find a new nest. These workers clearly benefit the future queen, a sister of theirs, and so altruism can spread through the colony. The reduced ovaries of the worker females mean that they have little chance to reproduce personally so that there altruism can be adaptive.

## Haplo-diploid Sex Determination and Indirect Selection

William Hamilton also thought that the method of sex determination of ants, bees, and wasps (all of which are placed in the order Hymenoptera) could have something to do with the evolution of helping by relatives in these groups. In the Hymenoptera, including the honey bee, males are haploid (have only one set of chromosomes donated by the mother), and females are diploid (with two sets derived from both parents) unlike most vertebrates in which both sexes are diploid and differences in sex chromosomes are the basis for sexual differences between males and females

(although in some species of turtles and crocodilians egg temperature determines the sex of the individual). Nevertheless female hymenopterans are unusual in being able to lay unfertilized eggs that develop into haploid males, whereas only fertilized female queens can produce diploid daughters.

Hamilton noted that the daughters of female queen hymenopterans that had mated with only one male would all receive that male's haploid set of chromosomes plus half of the mother's diploid makeup. The half received from the mother could be the same for two daughters or completely different for these two daughters or somewhere in between the same and totally different. As a result, the average similarity between two daughters would be  $\frac{1}{2}$  (from the father if the mother hymenopteran mated with a single male) +  $\frac{1}{4}$  (the average from the mother's genes) or  $\frac{3}{4}$ , a figure that is higher than that for diploid-diploid organisms where on average two offspring, whether daughters or sons, would have inherited half their genes in common from both parents. (See Rubenstein and Alcock for additional information on the significance of haplo-diploid sex determination.) If daughter workers possess  $\frac{3}{4}$  of the genes that reproductive females have, then helping future queens could be very adaptive

(genetically speaking) for sterile or male-producing wasps, bees, or ants. The same logic says that worker hymenopterans should make three times as many would-be queens as would-be kings, a prediction that has been found to be generally correct. Hamilton noted that in many Hymenoptera females do mate with just one male and that in these species female workers do tend to help reproductively competent sisters, as predicted, which supports the sex determination hypothesis for female altruism in this group of insects.

Hamilton understood, however, that diplo-diploid sex determination occurred in the termites, a group in which large numbers of altruists work together to build their often spectacular nests (Fig. 5). Others have taken this to mean that indirect selection was not necessary to produce helping behavior of the sort seen in wasps, bees, and ants. Still other observers have pointed out that the existence of termites does not mean that altruistic helping behavior depends on the haplo-diploid hypothesis. Instead altruism among relatives is common in both the Hymenoptera and the termites, suggesting that the benefits of the behavior, provided it is directed at relatives, need not be very great for the behavior to evolve. A net benefit is all the more likely for many social insects

**Sociobiology, Fig. 5** The huge mud nests built by workers of Australian termites showing that cooperation can occur among male and female insects whose sex determination is diplo-diploid unlike that of the bees, wasps, and ants

because the probability of direct reproductive success is so low for workers of this group as in the honey bee whose workers have very small ovaries and cannot reproduce sexually.

### Other Examples of the Utility of Indirect Selection as Explanations for Altruism

Research on bacteria has shown that individuals can recognize one another and behave positively toward those that are similar genetically unless there is competition for limited resources. Because bacteria often form colonies or clones of genetically identical individuals, altruism that costs the donor bacteria can spread if it benefits the recipients (provided that the recipients are closely related to the altruists as they would be in a clone). The release of a substance from the altruists that helps the receiver bacteria is the sort of behavior that could evolve by indirect selection. In fact, cooperation occurs not only among bacteria but also in a host of other situations including cooperation among organelles within an individual and the cooperation exhibited by different cells in the building of an individual. In many cases in which the organelles and cells are in the same body and have the same genes, the cooperation that exists between them represents indirect selection at work (West et al. 2007).

However, not all cases of altruism have a straightforward explanation. Thus, when starving slime molds cells come together in order to produce a stalk on which reproductive spores are situated, cooperation occurs in the growth of a stalk that does not participate in the production of spores, although the height of the stalk can influence the dispersal of the spores. When all this happens with genetically identical cells, the growth of a stalk can be explained as the result of altruism by cells that are genetically identical to the cells that will form the reproductive units of the slime mold. But when you artificially mix two clones, as sometimes occurs in nature, the two clones often contribute cells unequally to the non-reproductive stalk so that if 50% of the mixture is of clone A, the stalk may be made up of less than 50% of clone A cells. In cases in

which the stalk is largely composed of clone B cells, this suggests that clone A is exploiting clone B for its reproductive purposes (Strassmann et al. 2000). Thus the social behavior of clones of slime molds indicates that both direct and indirect selection are probably at work in determining the outcome of the stalk construction and the development of the spores, but the issue has yet to be fully resolved. When the issue of stalk formation is completely solved, Williams's and Hamilton's principles of genic selection will almost certainly be used by researchers studying the social behavior of slime molds.

### Conclusion

Despite the controversies associated with the early stages of sociobiology, the field has been producing ever more studies over the last 45 years, and it seems certain that it will flourish in the future. The work of G.C. Williams in showing that Darwinian theory is best used to develop and test hypotheses on how the social behavior of individuals enhances the reproductive success of individuals, and not the survival of social groups or species, has been critical in establishing the utility of sociobiology. In addition, the insights of W.D. Hamilton in demonstrating that individuals can propagate their genes indirectly, especially by helping relatives reproduce, have shown that genic selection is the key to understanding the evolution of social behavior of individuals whether mammals, birds, insects, or even bacteria. Together the two approaches have provided sociobiological researchers with two essential tools to explain why in evolutionary terms organisms have hit upon social life as a means to pass on their genes to future generations and so influence the evolution of social behavior.

## Definition

The term sociosexual behavior refers to behaviors that surround reproduction but are not directly related to copulation.

## Introduction

Sexual reproduction, or copulation, is nearly always preceded, and occasionally followed, by multiple forms of sociosexual behavior, which vary among species, within the same species,

and between sexes. Many sociosexual behaviors in the animal kingdom, through highly varied mechanisms among species, serve to increase the likelihood that copulation will take place with a desired mate. For example, in some species (e.g., gorillas, sea lions, and many arthropods), males engage in intense physical competitions with conspecifics for mates or territory where the winners exclude competitors, whereas in other species (e.g., birds of paradise), males will put on elaborate displays of physical beauty or behavioral prowess to attract a choosy female. The very fact that sociosexual behavior gives rise to perceivable differences in mates on the basis of genetic quality beautifully illustrates how sexual selection operates.

The evolution of sociosexual behavior tends to look remarkably different from species-to-species. However, a few generalizing hypotheses survive scrutiny when examined in the animal kingdom. For example, Trivers' Parental Investment Hypothesis (1972) predicts that the sex that invests more in the offspring (usually the female in mammals) will be choosier in selecting their mates. In species where this prediction holds true, it is expected that the sociosexual behavior from males will involve displays of fitness and mate quality, whereas the sociosexual behavior of females will be characterized by mechanisms for assessing these males with extreme care. To illustrate, the male golden-collared manakin (*Manacus vitellinus*) is a neotropical bird that will court females by jumping between branches and simultaneously "snapping" their wings together, hopping back-and-forth until they are deemed fit or unfit by a scrupulous female (Chapman 1935). The male of this species performs an elaborate and energetically costly display in order to convince a female that he has sufficient genetic quality with which to endow her offspring (Barske et al. 2011).

In a great number of species, however, females do not play a passive role in reproduction. Frank Beach (1976) described three aspects of sexual behavior in female mammals, attractivity, proceptivity, and receptivity, that can help us understand the conditions in which active female sociosexual behavior will arise. Attractivity refers

to the value of the stimulus that a female provides a male; proceptivity refers to the extent to which a female initiates copulation; receptivity refers to the response to male sexual initiation. Using this framework, it is easy to understand how female sociosexual behavior allows both choosiness and sexual solicitation. To illustrate, take the simple sociosexual behavior of female rats, known as lordosis. Lordosis refers to the posture a female rat adopts in which the back is arched and the genitals are presented to a male suitor and can indicate both sexual receptivity and proceptivity. A female rat that exhibits this behavior exercises female choice in that she may or may not present to a male rat. She can also advertise her own proceptivity by signaling to the male that she is ready to mate. Even this simple behavior exemplifies how sociosexuality increases the likelihood of copulation but with a particular desired mate. Again, in this view, sociosexual behavior acts as a major facilitator to differential reproductive success within a species.

Sociosexual behaviors do more than simply increase the likelihood that reproduction will occur with a desired mate. They also serve to increase future mating opportunities, to demonstrate dominance, and even to strengthen bonds (Paciulli and Emer 2018). In fact, some believe that strong pair bonds are formed and strengthened when evolved psychological mechanisms involved in social attachment are expressed during sociosexual interactions (reviewed in Johnson and Young 2015). That is to say, sociosexual behaviors such as touching, sniffing, and grooming in nonhuman primates serve to promote relationships, as well as to indicate sexual interest.

Sociosexual behaviors are often regulated by hormones and vice versa. Differences in hormones can give rise to differences in the frequency, intensity, and quality of sociosexual behaviors; therefore, hormones and behaviors give rise to differential reproductive success, a key requirement to the process of evolution. In some species, hormones are extremely influential to a specific sociosexual behaviors. For example, a Japanese quail (*Coturnix japonica*) that has been castrated (i.e., testes are removed, and testosterone production is eliminated) will exhibit hardly

any strutting or crowing behaviors that are critical for attracting and courting females. Even some sociosexual behaviors within mating systems, like monogamy, can be facilitated by hormones. For instance, in common marmosets (*Callithrix jacchus*), a primate that forms significantly strong pair bonds, the neurohormone oxytocin seems to reduce the likelihood of sociosexual behaviors that promote infidelity, such as sexual solicitation of strangers when the pair-bonded partner is not present (Cavanaugh et al. 2014); thus, oxytocin can keep marmosets from cheating on their partners.

Moreover, hormones can help explain the timing and intensity of sociosexual behaviors. In fact, female sociosexual behaviors in most mammalian species are intensified near ovulation when estrogen levels are high, relative to progesterin levels: a behavioral and physiological shift known as estrus. Bonsall et al. (1978) found that female rhesus macaques (*Macaca mulatta*) with high estrogen levels were more attractive, proceptive, and receptive than females with lower estrogen levels. Thus, female sociosexual behaviors are dependent not only on the presence of desired mates but also on their own likelihood of conception. In other words, why expend energy to produce sociosexual behaviors when they are unlikely to lead to offspring?

Hormones influence the sociosexual behaviors involved in male-male competition as well. Testosterone influences aggression that surrounds reproduction. Wingfield et al. (1990) proposed the challenge hypothesis, which states that testosterone increases when competing for mates and decreases when caring for offspring. This means that testosterone, and analogous androgens in other taxa, might mediate a male organism's allocation of energy toward different fitness efforts. Overall, sociosexual behaviors have deep evolutionary roots that are evident in the physiology of organisms that display them, and these evolved behaviors act to increase reproductive success, strengthen bonds, claim territory, and much more.

It should be briefly noted that the term *sociosexuality* holds a different meaning in research regarding humans. In human research,

sociosexual behavior refers to sexual behaviors that occur outside of a relationship, including sex itself. In fact, someone with high sociosexual *orientation* is considered to have a high propensity toward short-term mating experiences, or “casual” sex (Penke and Asendorpf 2008). Due to logic following parental investment theory, casual sex is considered an evolutionarily relevant mating strategy for males because they are not constrained to the lengthy period of gestation and increased metabolic requirements that apply to females and can therefore afford to be highly sociosexual and forego long-term relationships.

In summary, sociosexual behaviors are ubiquitous in sexually reproducing species. The amazing number of sociosexual behaviors and their numerous adaptive purposes are proof that evolution by sexual selection has the potential to do something as simple as join two gametes together in a seemingly infinite number of ways. The fact that sociosexual behaviors can be performed better or worse compared to conspecifics provides a strong theoretical framework from which to argue that each of these behaviors was shaped by the success of the organisms that first exhibited them.

## Somatic Cell Division

### ► Mitosis

## Somatic Cells

Elizabeth K. Mallott

Department of Anthropology, Northwestern University, Evanston, IL, USA

## Definition

Any cell in an organism that is not a reproductive cell.

## Introduction

Somatic cells are the cells of an organism that are not germ or stem cells. Somatic cells, germ cells, and stem cells have the same number of chromosomes. Somatic cells use mitosis as a method of cell division, while germ cells produce gametes after meiosis, usually in specialized reproductive structures or organs (Becker et al. 2003). Somatic cells are differentiated, having a specialized cell type, unlike stem cells.

## Follicle Cells

Follicle cells are a specialized type of somatic cells that are closely associated with germ cells. These cells are arranged as an epithelial layer around an oocyte and provide the oocyte with precursors for the macromolecules oocytes need to develop into an egg (Alberts et al. 2002).

## Gene Imprinting and X-Inactivation

In female mammals, one of the two X chromosomes is inactive in the somatic cells, known as X-inactivation. X-inactivation helps to regulate gene dosage, ensuring that gene derived products, such as proteins, are produced at the same rate in male and female offspring (Alberts et al. 2002). X-inactivation is achieved through gene imprinting.

Gene imprinting via DNA methylation during meiosis enables somatic cells with the same alleles to have different phenotypes in different individuals. The same allele of one gene in

different gametes is methylated differentially during meiosis, resulting in offspring with the same genotype but different phenotypes. DNA methylation can either turn a gene off or on in the individual's somatic cells (Alberts et al. 2002). Additional gene silencing via DNA methylation or other epigenetic mechanisms can also occur throughout development as somatic cells differentiate into different cell types.

### Somatic Doubling

Irregularities during mitosis in somatic cells can cause a numerical increase in the whole set of chromosomes within an individual, causing polyploidy. Polyploidy is when an individual animal has three or more sets of chromosomes instead of the usual two for that organism. If this occurs early in development or in somatic cells that give rise of reproductive cells, a polyploid individual can result (Losos et al. 2017).

### Mutations in Somatic Cells

Somatic cells accumulate variation throughout the life of an organism, but only variation in the germ line is inherited by offspring in eukaryotes. Mutations in somatic cells are not hereditary. However, mutations in somatic cells can have a deleterious effect on the entire organism. In mammals, cancer results from mutations in somatic cells. Often cancer occurs when a somatic cell line gains short-term advantages in growth and replication, to the detriment of the rest of the organism (Losos et al. 2017). Human somatic cells are deficient in telomerase, which causes chromosomal telomeres to shorten with each cell division (Alberts et al. 2002). This mechanism may help prevent runaway cell division that has the potential to lead to cancer.

### Induced Somatic Recombination

Induced somatic recombination is a technique used in developmental biology to analyze the function of different genes throughout development. This method allows mutations in groups of cells to be generated at a chosen time in order to

examine the effect of specific genotypes on development (Alberts et al. 2002).

## Songbird Duets

David M. Logue and Chinthaka D. Kaluthota  
Behaviour and Evolution Research Group,  
Department of Psychology, University of  
Lethbridge, Lethbridge, AB, Canada

### Definition

Duets are acoustic signals that occur when two individuals produce sound in temporal coordination with one another.

### What a Duet Is, and What It Is Not

Most songbird duets are produced by mated pairs, but there are exceptions (e.g., parent-offspring duets). Temporally coordinated vocal exchanges between competitors, such as counter-singing between neighbors, are not called duets. Duets can be contrasted with “solo” songs, which are produced by a single animal. Acoustic displays involving three or more animals are termed “choruses.” Choruses and mutual displays in non-acoustic modalities (e.g., dances) often resemble duets in both structure and function, but neither topic will be covered here.

### Research on Duetting in Songbirds

Duetting can be very conspicuous, so it is likely that people have been aware of it since prehistory. Scientific research on duetting began in the middle of the twentieth century. The period from the 1960s through the 1990s saw a steady trickle of duetting research, but it was not until the 2000s that duetting became a significant subdiscipline within birdsong research.

Most early research on songbird duets focused on structure and function (Hall 2009). Since the turn of the millennium, some functional hypotheses have garnered strong support while others

have fallen by the wayside. In the same time period, researchers have begun to elucidate the behaviors that structure duets, their ontogeny, and the evolution of duetting. As of this writing, research on the physiological and genetic mechanisms of duet singing remains sparse.

Both observational and experimental techniques have proven useful in duetting research. Observational studies describe duet structure, compare initiation and answering behavior over time, space, and singer class (e.g., sex, age), correlate duetting behaviors with other behaviors and contexts, apply the comparative method to answer questions about duet evolution, and analyze anatomy. Experimental studies include a variety of sound playback protocols (Douglas and Mennill 2010), mate removals and exchanges (Levin 1996), and physiological studies (Fortune et al. 2011).

### Description

A duet occurs when one animal (the initiator) produces an acoustic signal, and another (the answerer or responder) rapidly responds with an acoustic signal of its own. The proportion of the mate’s vocalizations that a bird answers is called the “answer rate.” After the first answer, one or both animals may continue answering to prolong a duet. The term “antiphonal” describes duets in which partners alternate phrases. The physical distance between duetting partners ranges from immediate proximity to the length of the territory.

### Timing

Whenever two birds are singing, some degree of temporal coordination can occur by chance. Randomization procedures can test whether the observed level of temporal coordination exceeds chance expectations (Masco et al. 2016). In many species, however, the partners’ phrases are so tightly coordinated that duets can be unambiguously identified without the need for statistical analysis. Initiation and answering rates vary

between sexes and over the breeding cycle. Answers may temporally overlap the partner's previous signal, or they may follow it. Temporal coordination is typically measured as variation in the relative timing of the partners' songs, with high variation corresponding to low coordination. In species that rapidly alternate duet phrases, the duration of silent gaps and overlapping phrases are considered measures of temporal coordination. Mates can improve their temporal coordination over the course of the pair bond (Rivera-Cáceres et al. 2016).

### Structure

In addition to temporal coordination, the contributions of partners are often also structurally coordinated. The vocal units that each individual contributes to a duet are called phrases, motifs, songs, or syllables (the nomenclature is not yet standardized). In many species, either sex can initiate a duet, but in others, males initiate all duets (Rogers 2005). A duet may comprise as few as two phrases, but many species sing longer duets. For example, white-crested laughing thrushes (*Garrulax leucolophus*) often sing duets with 20 or more phrases (Souček and Vencel 1975). Duet phrases are often identical to solo songs, but some songbirds produce duet phrases that are rarely or never sung as solos, and some contribute calls, rather than songs, to duets (Hall 2009). If both duetting partners sing repertoires of phrases, they typically combine phrases nonrandomly to form duets (Logue 2006). Thus, certain phrases from one partner tend to be combined with certain phrases from the other. In some species, the strength of the association between partners' phrase-types increases over the duration of the pair bond (Rivera-Cáceres et al. 2016).

### Visual Elements

Multimodal duets, combining visual and acoustic elements, seem to be more common in species in which partners are in visual contact when they duet. Visual elements, such as wing displays, may be temporally coordinated with duet phrases (Rek and Magrath 2016).

## Mechanisms

### Behavioral Mechanisms

The structure of a duet emerges from the rules that govern the singers' behavior. These rules can be studied observationally and with partner exchanges and experiments in which animals answer recorded stimuli. The timing of a duet phrase can be influenced by both the focal individual's own internal rhythm and the timing of the partner's previous phrase (Logue et al. 2008). There are similarities between the rules that govern the timing of duet phrases and the turn-taking rules that govern conversation in human beings (Ghazanfar and Takahashi 2014). Phrase choice can be influenced by both the focal bird's own previous phrase and by its partner's previous phrase. The set of rules that links the phrase-types a bird hears to the phrase-types it sings in response is called a "duet code" (Logue 2006).

### Physiological Mechanisms

Little is known about the physiological mechanisms that underlie duetting behavior. Variation in female song rates is more closely linked to variation in the aggression-linked hormone testosterone than it is to the reproduction-linked hormones estrogen and luteinizing hormone (Schwabl and Sonnenschein 1992). In plain-tailed wrens (*Pheugopedius euophrys*), whole duets are more neurologically salient than are solo songs (Fortune et al. 2011). The endocrine and neurological bases of duet song are promising areas for future research.

## Development

Songbirds learn the structural details of their songs. Therefore, species that use songs as duet phrases learn their duet phrases. There is now fairly strong evidence that some duetting species also learn temporal coordination and duet codes (Rivera-Cáceres et al. 2016). Further work is needed to clarify what is learned in early life and what is learned over the course of the pair bond.

## Functions

It is common for both members of a mated pair of songbirds to vocalize independently (Langmore 1998). Therefore, functional hypotheses about duetting must explain why partners temporally coordinate their vocalizations (i.e., why they answer their partners), rather than simply explaining why both partners vocalize (Hall 2009). Adaptive explanations for duetting behavior are often divided into “cooperative” and “conflict-based” hypotheses. Duet partners may reap different fitness consequences from participating in a duet, or even suffer costs as a consequence of their partner’s duetting behavior. For this reason, the functions of duetting behavior are usually best studied at the individual level (Hall 2009; Logue and Krupp 2016). Both duet participants and nonparticipants may perceive and respond to duets, so the possible functions of duet participation include both within-pair communication and extra-pair communication.

### Cooperative Hypotheses

#### Cooperative Territory Defense

In many species, duet participation functions to defend the mates’ shared territory. In this scenario, song answering tends to benefit both partners, even though the costs and benefits of territory defense may be asymmetrical. Evidence that duetting mediates cooperative territory defense includes (1) elevated answering rates during territorial encounters, (2) physical coordination between pair members during territory defense, (3) lower sex-specificity in territory defense among duetting species than nonduetting species, and (4) an evolutionary association between duetting and stable pair bonds (Benedict 2007; Hall 2009; Logue and Hall 2014; Tobias et al. 2016). With respect to their function in cooperative territory defense, duets are functionally similar to other collective acoustic signaling behaviors, such as roaring in lions (McComb et al. 1994).

#### Spatial Localization

Tropical wrens use duet contributions to acoustically locate their partners in their forest habitat

(Logue 2007; Mennill and Vehrencamp 2008). The bird that initiates the duet tends to move toward the bird that answered, suggesting that initiation functions to solicit an answer, and answering facilitates localization. The phylogenetic extent of this function is not known, but it stands to reason that spatial localization is not an important function of duet participation in species that are in visual contact when they duet. The localization function of duetting alone cannot explain why duets have evolved to high levels of complexity and temporal coordination in some species (Hall 2009).

#### Pair Bonding and Reproductive Synchrony

There is little empirical support for the ideas that duetting strengthens the pair bond or helps mates synchronize their reproductive efforts (Hall 2009). A notable exception is zebra finch (*Taeniopygia guttata*) duets, which are too quiet to serve as resource defense signals, but may permit individual recognition and the coordination of reproductive behavior (Elie et al. 2010).

### Conflict-Based Hypotheses

#### Mate Guarding

When a bird answers its mate, the answer may repel same-sex rivals who would otherwise attempt to pair with the mate. It has proven difficult to test predictions of this hypothesis that are not also predictions of the territory defense hypothesis (Hall 2009). According to both hypotheses, song answering should repel (potential) intruders. The distinction between the two hypotheses concerns the consequences of failing to answer. If failure to answer increases the probability of territory loss, answering functions for territory defense. If it increases the probability of mate loss, answering functions of mate guarding. If failure to answer increases the probability of both mate loss and territory loss, both hypotheses would be supported. The notion that mate guarding is a conflict-based hypothesis rests on the assumption that the answered bird would benefit from switching mates. If that is not true, mate guarding could be considered cooperative,

as described by the “pair-bond maintenance” hypothesis of duet function.

The best evidence for a mate guarding function of duet participation in a songbird comes from the eastern whipbird (*Psophodes olivaceus*). Females of that species compete for access to territorial males and answer at elevated rates when threatened by other females (Rogers et al. 2006).

#### Paternity Guarding

According to the paternity guarding hypothesis, male answers repel male rivals who would otherwise attempt to copulate with the answerer’s mate. Contrary to a key prediction of this hypothesis, most studies have not found increased male answer rates during the mate’s fertile period (Hall 2009).

#### The Functions of Structural Coordination and Fine-Scale Temporal Coordination

Elaborations on simple song answering, like adherence to duet codes and fine-scale temporal coordination, are generally assumed to have functional significance. Adherence to a duet code has been proposed to signal pair bond strength or duration, indicate attentiveness to the mate, improve fine-scale temporal coordination between duetting partners, and serve as a system of passwords for individual recognition (Hall 2009). None of these hypotheses have been tested directly, but the finding that code adherence can improve over the course of the pair bond lends credence to the idea that it signals pair bond duration (Hall and Magrath 2007; Rivera-Cáceres et al. 2016).

The main functional hypotheses for fine-scale temporal coordination are that it (1) signals pair bond strength or duration and (2) indicates attentiveness to the mate. The first hypothesis is supported by studies showing improved coordination over the course of the pair bond and differential responses to playback of coordinated versus uncoordinated duets in some (but not all) species (Hall and Magrath 2007; Kovach et al. 2014; Rivera-Cáceres et al. 2016). The attentiveness hypothesis has not been tested.

#### Evolution

Many non-oscine birds duet, as do some anurans (frogs and toads), insects, and mammals (especially primates). Among songbirds, duetting is associated with tropical and southern hemisphere breeding, the absence of migration, and long term pair-bonds. Breeding latitude and migration appear to influence the stability of pair-bonds, which directly influences duet evolution (Tobias et al. 2016). Duetting is widespread in the songbirds, having evolved several times. It exhibits phylogenetic signal, so certain lineages are rich in duetting species, whereas others are depauperate (Logue and Hall 2014). Duet structure varies among clades of duetting wrens, but the degree to which this is true of other duetting groups remains an open question (Mann et al. 2009).

The total diversity of duetting songbirds is estimated at 15.6% of species and 43.8% of families (Logue and Hall 2014). Those percentages project to approximately 700 species in 30 families. Songbird families that are known to include multiple duetting species include the babblers (Timaliidae), bushshrikes (Malaconotidae), cisticolas (Cisticolidae), New World blackbirds (Icteridae), honeyeaters (Meliphagidae), New World sparrows and allies (Emberizidae), Old World warblers (Sylviidae), shrikes (Laniidae), starlings (Sturnidae), tanagers (Thraupidae), vangas (Vangidae), weavers (Ploceidae), and wrens (Troglodytidae).

#### Conclusion

Vocal duetting is widespread in songbirds. It is also diverse, with structures that range from simple call-and-response to long and complex phrase sequences. Duetting behavior serves multiple adaptive functions within and between species, but cooperative territory defense is an important function in most species that have been tested. Recent years have seen significant advances in research on the diversity, function, and evolution of duetting, as well as the behaviors that structure duets. Research on the genetic, neural, and

endocrine mechanisms of duetting, however, is still in its infancy.

Knowledge about duetting has at least two important implications outside of the field of animal communication. First, song answering is a model cooperative behavior that can be used to address hypotheses about the plasticity and evolution of cooperation in general. Second, duetting is the best animal model of complex vocal interaction. As such, duetting research has the potential to improve understanding of the behaviors and physiological mechanisms that underlie vocal interaction. Advances in the field could have implications for the study of human conversation, the development of artificial communication systems, and the treatment of pathologies that affect communication.

## Songbird Learning

Chinthaka D. Kaluthota and David M. Logue  
Behaviour and Evolution Research Group,  
Department of Psychology, University of  
Lethbridge, Lethbridge, AB, Canada

### Synonyms

[Song learning in songbirds](#)

### Definition

Songbirds belong to suborder Passeri (or Oscines), in the order Passeriformes (perching birds). Members of this group learn the structural details of their songs by listening to the songs of conspecifics.

### Introduction

Vocal learning describes the process of learning to produce vocal signals by listening to similar vocalizations. Animals that exhibit vocal learning

include humans, bats, whales and dolphins, elephants, and birds. Among the birds, there are three groups of vocal learners: parrots, hummingbirds, and songbirds. Songbirds are by far the most diverse and best-studied group of vocal learning birds. For centuries, humans have taken advantage of songbirds' remarkable capacity for vocal learning by training species such as canaries and nightingales.

All bird vocalizations are classified as either calls or songs. In general, songs are more elaborate and, in the case of songbirds, learned, whereas calls are simpler and innate. Relative to other passerines, songbirds have distinctive brain structures and syringeal anatomy that facilitates song learning and the production of complex songs.

Bird songs comprise of combinations of sound elements and can last anywhere from a few seconds to several minutes. Groups of sound elements that always occur together in a certain order are called syllables. Syllables are typically delivered in a particular order to form songs. Based on the types of syllables and their order, songs can be categorized into song types. The set of song types an individual sings is that individual's song-type repertoire. Some birds have very simple song structures with minimal number of sound element types. For example, individual chipping sparrows (*Spizella passerina*) sing a single song type, consisting of only a single element type repeated many times. At the other extreme are species such as the house wren (*Troglodytes aedon*), in which each individual produces many different song types, each of which contains several types of syllables.

### History of Research

#### Classical Work

The beginning of the modern scientific study of song learning in birds can be attributed to W. H. Thorpe who studied common chaffinch (*Fringilla coelebs*) songs in the middle of the twentieth century (Thorpe 1958). He raised young chaffinches in isolation, which prevented them from hearing any adult chaffinch song. When the

isolated birds matured, their songs were different from typical chaffinch songs. This result suggested that learning models (“tutors”) are necessary for normal song development.

In an experiment on dark-eyed and yellow-eyed juncos (*Junco hyemalis*, *Junco phaeonotus*), Masakazu Konishi showed that artificially deafened males fail to produce species-typical songs (Konishi 1964). He went on to conduct similar experiments on other species and found the same effects of deafening on song learning. Fernando Nottebohm showed that chaffinch males deafened as nestlings fail to develop normal song, but those deafened as adults continue to sing normally (Nottebohm 1969). Peter Marler and Susan Peters (1977) found that young swamp sparrows (*Melospiza georgiana*) exposed to both swamp sparrow and song sparrow (*Melospiza melodia*) songs ultimately learned only their species-specific songs. Marler (1970b) exposed young white-crowned sparrows (*Zonotrichia leucophrys*) of different ages to adult singers of the same species and found that there is a sensitive period early in the bird’s life during which song learning occurs.

These pioneering studies established that young songbirds learn songs by listening to adults of their own species at a critical sensitive period in their first year of life, laying the foundation for the study of song learning in songbirds.

### Model Species

There are extensive parallels between song learning in songbirds and language acquisition in humans (Bolhuis and Everaert 2013; Marler 1970a). For example, both taxa have a sensitive period in early life, “babble” before producing mature vocalizations, avoid learning species atypical sounds, and learn both sounds and transitions between sounds (Lipkind et al. 2013). Because of these similarities, songbirds are models for research on vocal learning.

For practical reasons, the majority of song learning research involves laboratory experiments. These studies tend to focus on species that can be bred easily and raised in laboratory conditions. Most of the experiments carried out in Europe have been focused on species like the common chaffinch, common nightingale (*Luscinia*

*megarhynchos*), and European starling (*Sturnus vulgaris*). North American studies have mostly been based on the song sparrow, swamp sparrow, white-crowned sparrow, and zebra finch (*Taeniopygia guttata*). Recent advances have allowed field-based studies of vocal learning and expanded the taxonomic reach to include species like blackbirds, wrens, and mockingbirds.

### Current Research

Early research on song learning was focused on describing the learning process in male songbirds from the temperate zone. Later studies explored the physiology, genetics, and neuroscience of song learning, revealing many mechanistic similarities between song learning in songbirds and human language acquisition. Recently, researchers have turned their attention to vocal learning in tropical songbirds and females, as well as social influences on learning.

### The Evolution of Song Learning

The approximately 11,000 known living bird species belong to 36 orders (del Hoyo and Collar 2014, 2016), only three of which learn their vocalizations. Songbirds (suborder Passeri, order Passeriformes) comprise nearly half of all bird species. Parrots (order Psittaciformes) and hummingbirds (family Trochilidae, order Caprimulgiformes) are the other two groups of birds that are known to learn the structural details of their vocalizations. There exist remarkable similarities in the brain regions that support vocal learning in all three taxa. Based on these findings, three different hypotheses have been proposed to describe the evolution of song learning (Jarvis 2006).

The first hypothesis suggests that vocal learning evolved twice independently, in hummingbirds and in the common ancestor of parrots and passerines, circa 65 million years ago. An alternative hypothesis proposes that the common ancestor of all three vocal learning groups was a vocal learner, and learning was subsequently lost in several lineages. According to the third hypothesis, both vocal learners and non-learners possess rudimentary versions of the brain nuclei necessary

for vocal learning, but the ancestors of the three vocal learning groups independently evolved enlargement of these brain structures, facilitating vocal learning.

## Song Learning in Female Songbirds

Female song is rare in most North temperate songbirds but common in the tropics and Southern Hemisphere. The ancestor of all extant songbirds had female song, so lineages with male-only song have lost female song over evolutionary time (Odom et al. 2014). Like male song, female song functions in territory defense, especially in female-female competition. Females may also sing to solicit extra-pair copulations, court their partner, or maintain pair bonds. Females often sing in temporal coordination with their mates, a behavior called “vocal duetting.” While it is clear that female songbirds learn their songs, very little is known about how singing females learn songs. Existing evidence, however, suggests that the process of female song learning is similar to that of male song learning (Evans and Kleindorfer 2016; Riebel 2016). Females also learn about conspecific songs that they do not sing. This kind of learning influences females’ song preference in adulthood. Sexual dimorphism in the song learning process, tutor-tutee relationships, and learning efficiency requires further investigation.

## The Adaptive Significance of Song Learning

There are several possible answers to the question, “why have songbirds evolved to learn their songs?” Among the leading hypotheses is that song learning facilitates the elaboration of both songs and song repertoires. More complex songs and larger repertoires are more attractive to females in some species and may be more effective for excluding territorial competitors (Catchpole and Slater 2008). The “mate choice hypothesis” states that female choice drives the evolution of large song repertoires. In many species, females prefer to mate with males that sing

large song repertoires (reviewed in Catchpole and Slater 2008 but see Byers and Kroodsma 2009 for a dissenting view). By preferentially mating with males with large repertoires, females may have selected for song learning ability.

Alternatively, song learning may be an adaptation for interactive vocal communication between neighbors. Territorial neighbors often sing back-and-forth to one another. This behavior, known as counter singing, is believed to mediate territorial disputes. Birds may song-type match (sing the same song type), repertoire match (sing a song from the neighbor’s repertoire), or avoid matching the song or repertoire of their neighbor to mediate territorial aggression. According to this hypothesis, both forms of matching serve to escalate contests, and nonmatching signals an intention to de-escalate. Song learning gives birds the ability to sing both shared and unshared song types.

Once vocal learning is widespread, learning proficiency could evolve to be a reliable indicator of developmental stress, such as malnutrition in early life (Nowicki et al. 1998). Accordingly, a male’s song structure might indicate his phenotypic quality and influence how females or rivals interact with him. Similarly, learned songs could allow females to choose genetically compatible males, assuming that genotypes covary with song structures. For example, females might memorize their father’s songs and go on to choose mates with similar songs. Evidence for this hypothesis is mixed.

## An Overview of the Learning Process

The “auditory template model” of song learning was proposed to explain how young birds learn their songs from adult conspecifics. The model has been modified in light of recent findings, but it continues to inform scientists’ understanding of song learning and makes a useful jumping-off point for discussions of song learning.

The auditory template model states that newly hatched birds already possess a crude template of their species-specific song. Within the first few weeks of life (the exact timing depends on the species), birds enter a “sensitive period,” during

when they attempt to match the sounds they hear with their innate template. Template matching enables birds to further refine their innate template and to filter out sounds other than conspecific song. During their sensitive period, young birds memorize their songs but do not sing them. The period when song production occurs, known as the “motor phase,” generally occurs later in the next spring. In some species, however, the memorization and motor phases overlap (Catchpole and Slater 2008).

Songbirds generally start to sing within the first year of life, often in their first spring. During the motor phase, birds match the sounds they produce with the template they formed during the memorization phase. The process of matching the song to the template takes time. Over the course of the motor phase, vocal output passes through several stages. The first kind of vocal output during the song development process is called “sub song.” Sub song comprises a highly variable set of sound syllables with no or little repetition. Sub song is generally much quieter than adult song, and syllables sung at this stage bear little similarity to typical song syllables in adults. Marler (1970a) equated sub song to babbling in human babies during the early stages of language acquisition.

During the second stage of song development, named “plastic song,” birds sing louder, more structured songs. Relative to sub song, plastic song is less variable and more similar to typical adult songs in terms of both structure and duration. Songs gradually start to resemble species-typical adult songs in all aspects. Finally, “crystallized songs” represent fully adult, species-typical songs. The term “crystallized song” is somewhat misleading, because song structure can continue to change in adulthood in many species (see below).

### When, What, and from Whom Do Birds Learn?

This section builds on the auditory template model to provide a more nuanced view of song learning in oscine passerines.

### When Does Learning Occur?

The sensitive period typically begins after fledging, but some vocal learning may occur earlier in certain species (Colombelli-Négrel et al. 2016). Sensitivity to vocal inputs changes over the course of the sensitive period, and the total duration of the sensitive period varies widely among songbird species (Catchpole and Slater 2008). Some species have short sensitive periods (e.g., 50 days in white-crowned sparrows, 1–3 months in zebra finches). Other species have extended sensitive periods (e.g., 5 months in song sparrows). Species with restricted sensitive periods are known as “closed-ended” or “age-limited” song learners. Still other species have sensitive periods that extend beyond their first year of life. Nightingales and marsh wrens (*Cistothorus palustris*) learn new songs in the spring after their hatch year. The European starling is an example of a species that has been termed an “open-ended” learner, because it memorizes and produces new songs throughout adulthood. It is now known that vocal learning often extends beyond the first year of life and that extended sensitive periods are more commonly observed in the wild than in laboratory studies, even when controlling for species (Catchpole and Slater 2008). Close-ended and open-ended learning styles should not be seen as a dichotomy but rather as endpoints on a continuum (Brenowitz and Beecher 2005).

### Practice, Improvement, and Attrition

During the motor phase, young birds practice their songs while listening to their own song output, leading to the term “sensory-motor phase.” Auditory feedback (hearing one’s own song) is required to accurately recreate the memorized songs. Various other factors affect song development process in both sensory and sensory-motor phases. For example, sleep plays a critical role in song learning. The song nuclei in the brains of sleeping zebra finches are active during the sensory-motor phase of song learning (Dave and Margoliash 2000), suggesting that young birds replay songs in their sleep. Improvement in song copying occurs immediately after sleep, further indicating the role of sleep in consolidating vocal learning (Derégnaucourt et al. 2005).

Song development in birds is also affected by early nutrition (Nowicki et al. 1998). Nutritional stress in early life may affect neurogenesis in the brain and thus the song learning process. As a result, song structure and singing behavior in adulthood may reflect the bird's nutritional state in early life.

During the plastic song stage, birds sing many songs and song elements that do not end up in the crystallized repertoire (Catchpole and Slater 2008). For example, a swamp sparrow's plastic song includes four to five times the number of song elements as his crystallized song repertoire. The process of losing songs or elements is called attrition. The selective attrition hypothesis suggests that birds selectively eliminate some elements or song types and retain the most useful songs into adulthood (Nelson and Marler 1994). Social cues are thought to influence which songs will be retained (e.g., those that permit song matching with neighbors).

### What Is Learned?

Some songbird species sing only a single song type throughout their lives, but there are many species in which individuals can sing more than one song type. For example, a white-crowned sparrow generally sings one or two song types, whereas a song sparrow can sing up to ten song types. Individuals of some other species, like sedge wrens (*Cistothorus platensis*) and house wrens, can produce hundreds of song types. Brown thrashers (*Toxostoma rufum*) sing over 1500 song types.

Songbirds not only copy single songs accurately, they also learn how to sing songs in specific sequences (Marler and Slabbekoorn 2004). Similarly, duet-singing species learn to link their own songs with the songs of their duet partners to form specific sequences. In species with large repertoires, like nightingales, songs are organized in the memory as sub-repertoires. Birds associate these sub-repertoires with contexts, including locations and times (Marler and Slabbekoorn 2004). At a finer scale, birds can learn how to order song syllables independently of learning the syllables themselves (Lipkind et al. 2013; Rose et al. 2004).

### From Whom Do Birds Learn?

After fledging, but before dispersing from the natal territory, young birds are accompanied and provisioned by one or both parents. They may learn songs from their parents and neighbors during this time. Young birds continue to encounter other singing conspecifics after postnatal dispersal, providing opportunities to learn different songs. Species with extended sensitive periods can also learn from neighbors after their territory establishment, facilitating the ability to song-type match and repertoire match neighbors.

Early studies on song learning were conducted under laboratory conditions. Researchers played audiotapes of adult songs to tutor young birds. Later, it was discovered that tape-tutored birds learn differently than live-tutored birds. Importantly, live tutoring tends to extend the sensitive period, and young birds are generally more responsive to live tutors than they are to tape tutors. Indeed, some species never learn from tape tutors. It is now clear that social interactions are critical to the song learning process and that both direct and indirect interactions (e.g., eavesdropping on counter-singing neighbors) with tutors influence learning (Beecher 2016).

### Song Mimicry

The innate auditory template and strong social association with conspecifics generally ensures that birds will learn species-typical songs. Some birds, however, learn other species' songs. The inclusion of hetero-specific elements in the song repertoire, termed "song mimicry," can be pathological (e.g., when a young bird accidentally learns a song that is not typical of its species), but it can also be adaptive. For example, some species include the call notes of other species in their songs, which allows them to recruit birds of those species when mobbing a predator. Drongos (family Dicruridae) recruit other species to mixed-species feeding flocks by mimicking their songs. Males of the brood-parasitic indigobirds (family Viduidae) sing the songs of their host species, which they use to attract female indigobirds. Extreme examples of mimicry by Australian lyrebirds (family Menuridae) demonstrate the capacity of avian vocal

learning. These species mimic not only other songbird species but also many other species including mammals, as well as anthropogenic sounds such as sounds of chain saws, cameras, and car alarms. They use mimicry during courtship and male-male encounters.

## The Endocrinology of Song Learning

Testosterone has important effects on song learning and production (Arnold 1975). In species with male-only song, testosterone causes young males to produce more neurons in the song nuclei of the brain than do females. Castrated males do not sing unless they are supplemented with testosterone, and testosterone supplementation can induce song in females of species that do not typically have female song. Seasonal changes in testes size affect testosterone production in male birds and mediate seasonal variation in song production. Oxytocin may also play a role in song learning (Theofanopoulou et al. 2017).

## The Neuroscience of Song Learning

Zebra finches and other songbirds are the primary animal models for neuroscientific research on vocal learning. As such, the neuroscience of song learning is a large, active field (Jarvis 2006).

### Brain Regions

Song learning and song production are governed by several specialized brain regions (or “nuclei”) and connecting pathways. Collectively, the nuclei and pathways are known as the “song system.” The songbird song system contains two main branches, known as the “posterior descending pathway” (PDP) and the “anterior forebrain pathway” (AFP). The PDP, which is also known as the “motor pathway,” is responsible for song learning and production. The AFP functions exclusively in song learning. Central to both of these pathways is the nucleus known as the HVC. That area used to be called the “hyperstriatum ventrale, pars caudalis” and, later, the “high vocal center,” but those names were determined to be inaccurate, so

HVC is now a pseudo-acronym that does not stand for anything.

The PDP is made up of the HVC, the robust nucleus of the arcopallium (RA), and the tracheosyringeal component of the hypoglossal nucleus (nXIIts). The AFP comprises the HVC, Area X, the medial portion of the dorsolateral thalamic nucleus (DLM), the lateral part of the magnocellular nucleus of the anterior nidopallium (LMAN), and the RA. Both the PDP and the AFP are small in nestlings and increase in size, number of neurons, and connections as young birds learn to sing.

In many species, males have more and larger neurons and higher number of neuronal connections in the song nuclei than do females. These anatomical differences typically correspond to sex differences in singing behavior. Unsurprisingly, sex hormones influence the early stages of development of song nuclei. For example, young female zebra finches that are supplemented with testosterone develop male-like song nuclei and express song.

The discovery of adult neurogenesis in song control regions had important implications in the neuroscientific community, which was skeptical of adult neurogenesis at the time. Adult neurogenesis occurs in certain song nuclei, such as the HVC and Area X, but not in others. Many songbirds exhibit seasonal variation in both the size and number of neurons in these regions. High song rates, as occur in the early spring, are hypothesized to induce neurogenesis. However, the precise relationship between singing behavior and changes in neurogenesis is still not characterized well through systematic studies. Similarly, the functions of adult neurogenesis in song nuclei are not known, but hypotheses abound (Brenowitz and Larson 2015). For example, adult neurogenesis may enable birds to learn and produce new songs, to learn to recognize new songs, or to replace old neurons.

### Auditory Feedback

Birds must hear their own songs to develop normal songs and maintain crystallized songs. The “auditory pathway,” which includes seven brain nuclei and connecting pathways, is responsible for this task. The “Caudal Medial Nidopallium”

(NCM) in the auditory pathway is responsible for long-term memory of songs learned in early life (Yanagihara and Yazaki-Sugiyama 2016). Auditory regions and the HVC in both males and females are sensitive to their own species' songs. Several competing hypotheses have been proposed to explain how auditory input influences the vocal pathway, but this issue has not yet been resolved (Marler and Slabbekoorn 2004).

### Mirror Neurons

Mirror neurons are involved in song production, the perception of the bird's own song, and the perception of other conspecifics' songs. They play a role in song learning, perception, and singing activities, such as song-type matching (Mooney 2014).

### Gene Expression in the Brain

A number of genes have been identified as playing major roles in song learning and song production. Patterns of gene expression in song nuclei vary across the stages of song learning and across seasons. Singing induces expression of the immediate early gene ZENK in both the vocal pathway and the auditory pathway, which in turn influences the expression of other genes involved in song production. The FOXP2 gene plays a major role in vocal development in both songbirds and human beings. FOXP2 is expressed in Area X in the anterior forebrain pathway. Knocking down FOXP2 expression results in abnormal song development in zebra finches. A similar pattern is observed in humans, where mutated FOXP2 gene results in incomplete and inaccurate word copying and poor pronunciation (Bolhuis and Everaert 2013). FOXP2 expression changes seasonally, with elevated expression when birds add new song elements after the breeding season.

### Cultural Evolution and Song Dialects

The songs of a population of songbirds, which themselves comprise a population of songs, change over the course of generations. In other words, populations of songs evolve. Because songs are transmitted by learning rather than by

genetic inheritance, this represents a form of cultural evolution. Cultural evolution has many similarities to biological evolution. Both processes generate diversity, and both are influenced by mutation, drift, selection, immigration, and emigration.

De novo generation of song elements and song types are analogous to genetic mutation, in that both processes introduce novel variants into a population. Copying errors, including insertions, duplications, deletions, or transpositions of song elements, can occur at various stages of the song learning process. If these errors are passed on to other birds, they introduce novel variation into the song population. Novel song variants can also come from mimicry, improvisation, and immigration. Songs that are copied more or less than others because of their properties (e.g., their ability to transmit over long distance or their effectiveness at repelling rivals) are under cultural selection. The frequency of a song variant that is not under selection is expected to vary randomly over time, like allele frequencies undergoing genetic drift.

Like biological evolution, cultural evolution produces geographic variation. The term "song dialect" describes discrete geographical variants of learned birdsong. Dialects are a result of vocal learning. They also occur in other vocal learning species, such as parrots, hummingbirds, whales, and human beings. Dialects are more pronounced among species with small repertoires (Price 2008). White-crowned sparrows, which have very small repertoires (often just one song type), form dialects with discrete geographical boundaries (Marler and Tamura 1964). Although repertoires often vary geographically in large-repertoire species, they tend not to form geographically discrete dialects.

Young birds of both sexes are exposed to their own song dialects, but they do not typically hear foreign dialect songs. As a consequence, adult songbirds could fail to recognize foreign songs as belonging to conspecifics. In general, male birds tend to respond more aggressively to the playbacks of their own dialects. Females tend to prefer local songs to foreign ones in laboratory-choice experiments. In theory, this kind of

preference pattern could drive genetic evolution. Recognition of foreign songs could be facilitated by features that cross-dialect boundaries, such as the whistle notes at the beginning of white-crowned sparrow songs.

A key question is whether song dialects are barriers to gene flow. If they are, dialect formation could drive reproductive isolation, ultimately leading to speciation. The data are mixed. Some evolutionary models suggest that song learning accelerates the speciation process. It is clear, however, that dialects are not always associated with genetic structure (Slabbekoorn and Smith 2002). As song learning plays a major role in song divergence and promotes premating isolation, song learning is hypothesized to be one of the driving forces of rapid speciation in Oscines. However, diversification rate of songbirds is slower when compared with some other rapidly diversified clades such as sub-Oscines and order Ciconiiformes (storks and allies), which do not possess the ability of vocal learning (Price 2008).

## SOP Model

Edgar H. Vogel<sup>1</sup> and Allan R. Wagner<sup>2</sup>

<sup>1</sup>Facultad de Psicología, Universidad de Talca, Talca, Region del Maule, Chile

<sup>2</sup>Yale University, New Haven, CT, USA

The Sometimes Opponent Processes (SOP) model of Pavlovian conditioning was proposed by Wagner (1981; see also Mazur and Wagner 1982) as quantitative elaboration of Priming Theory (Wagner 1976). This theory states that the effectiveness of a Pavlovian conditioned stimulus (CS) or unconditioned stimulus (US) to produce its response or to develop an association with other stimuli is diminished when the stimulus is already represented in active memory at the moment of presentation. This priming can be a consequence of a recent presentation of the stimulus (self-generated priming) or of retrieval of its representation from memory by an associated stimulus (associatively generated priming). This idea can explain several related phenomena, such as the observation of diminished reinforcement and diminished vigor of the unconditioned response provoked by the presentation of an unconditioned stimulus that has been shortly preceded by itself or by an associated conditioned stimulus. Wagner (1976) suggested that the observed diminution in responding to a repeated stimulus or habituation is generally to be understood in such unified fashion: there is a transient memorial effect, due to recent exposure to the stimulus, and there is a more persisting memorial effect due to the context acting as a conditioned stimulus.

According to SOP, the memory system comprises a set of representational nodes, each distinguished by its predominant state of activity and by the directional excitatory and inhibitory linkages

that exist with other nodes. The model includes rules of nodal activity and rules by which conjoint activity produces changes in the existing linkages between nodes. An individual node representing an experimental stimulus (conditioned or unconditioned) is assumed to be formed by a large collection of elements that can be in one of three states of inactivity (I), primary activity (A1), or refractory activity (A2). Upon presentation of the corresponding stimulus event, a proportion of inactive elements are promoted to the A1 state, according to the momentary probability  $p1$ , from which they subsequently decay, first to the A2 state, with probability  $pd1$ , and then back to inactivity with probability  $pd2$ , and in which they remain for as long as the corresponding stimulus remains absent. Thus, the only momentary effect of a novel or untrained stimulus on its memory node is to activate a given proportion of the then-inactive elements to the A1 state with no effect on the elements that are already in the A1 or A2 state.

The global activity of each stimulus in time is characterized by the momentary proportion of elements in the A1 and A2 states of activity. Formally, changes in the proportion of elements in the primary state of activity are given by  $\Delta A1_i = p1_i[1 - (A1_i + A2_i)] - [pd1_i A1_i]$  and changes in the proportion of elements in the secondary state of activity are given by  $\Delta A2_i = [pd1_i A1_i] - [pd2_i A2_i]$ . These rules produce quite regular curves of expected A1 and A2 activity over time after stimulus presentation, involving a progressive increase in A1 activity, which is proportional to  $p1$ , followed by a progressive increase in A2 activity which is proportional to  $pd1$ . Both A1 and A2 activity decays progressively towards zero after stimulus offset.

According to SOP, both excitatory learning and inhibitory learning occur separately and result from concurrent activation of the conditioned and unconditioned stimuli. Increments in the excitatory CS-US links,  $\Delta V^+$ , are assumed to be proportional to the momentary product of concurrent  $A1_{CS}$  and  $A1_{US}$  activity multiplied by an excitatory learning rate parameter,  $L^+$ , (i.e.,  $\Delta V^+ = L^+ A1_{CS} A1_{US}$ ), whereas changes in the inhibitory CS-US connections,  $\Delta V^-$ , are assumed to be proportional to the momentary product of concurrent  $A1_{CS}$  and  $A2_{US}$  activity, multiplied by

an inhibitory learning rate parameter,  $L^-$  (i.e.,  $\Delta V^- = L^- A1_{CS} A2_{US}$ ). The result of an acquired associative tendency is to allow initial activity of the respective CS representation to provoke some A2 activity in the US node (if net  $V$  is excitatory) or to suppress other associative activation of the US node (if net  $V$  is inhibitory). There may be multiple CS nodes active at any moment, each with its own balance of excitatory and inhibitory associations with the US and with its own momentary distribution of activity of its elements. The model assumes that any CS node influences the US in accordance with the product of its momentary  $A1_{CS}$  activity and the net value of its associative connection with the US. These products are summed over all CS representations to determine the value of a variable named  $p2$ . Formally,  $p2_{US} = \sum A1_i V_i$ .

SOP assumes that the presentation of the US provokes a first component of the unconditioned response, which depends on the proportion of US-primary activity and then a second component, dependent on US-secondary activity. The two response tendencies can be similar, as is the case of the eyeblink response to a paraorbital shock, both contributing to the net response, but they might also be assumed to be antagonistic or unrelated to one another in other response systems. The CS has its influence on behavior by provoking  $A2_{US}$  activity by means of its associative link. The direct effect is an anticipatory response that can add or oppose to the unconditioned response occasioned by a subsequent US. By this action of moving US elements directly to the A1 state, the CS has also an indirect behavioral consequence, which is decreasing the A1 activity occasioned by a subsequent presentation of the US. Consequently, the acquired CS-US association influences not only the probability of the response, but also the processing of the US. Thus, if the A2 node of a US is activated by the precedence of an associated CS (associatively-generated priming) or by itself (self-generated priming), the A1 node of that US will be less susceptible to activation, so as to produce not only a diminished UR but also less associative learning. These assumptions were formalized by Wagner (1981) by stating that the unconditioned response is given by:  $UR = f(w1 A1_{US} + w2 A2_{US})$ ,

where  $f$  is a function representing each response system, and  $w_1$  and  $w_2$  are differential weights for the contribution of A1 and A2 to the response.

Since its original formulation, the SOP model has evolved to consider more complex or componential representations of the experimental stimuli. The AESOP model (Wagner and Brandon 1989) proposed how the divergence of conditioned response measures might be described by parametric differences in the state transitions associated with nodes representing the emotive (e.g., fear) as contrasted with the sensory (e.g., eye-blink) aspect of a given US (e.g., paraorbital shock). Subsequently, Brandon and Wagner (1998) conjectured how phenomena of occasion setting might be attributed to discriminative control by different nodes of the conditioned stimulus that represent conjunctive and unique aspects of the stimulus, a notion that was further elaborated in the SOP-REM model (Wagner and Brandon 2001; Vogel et al. 2017). Likewise, Vogel et al. (2003) explained the observation of differential CR timing that results from training with different CS-US intervals by proposing that different elements representing a CS might differ in their temporal dynamics so as to be more or less conjunctive with activity produced by the US. All of these proposals share the added presupposition that the representation of the stimuli should be componential rather than molar; but, beyond that, they retain the rules and principles of the original SOP model.

## Definition

Time-frequency visual representation of an auditory signal.

## Introduction

Animals produce a wide range of vocalizations and mechanical sounds that may be used to communicate their identity, fitness, willingness to mate, location, food availability, or possible danger. Visualizing these auditory signals is critical for understanding their role in animal cognition, communication, and behavior. The spectrogram, or a time-frequency depiction of sound, is a fundamental tool in the study of animal behavior. Prior to the invention of the spectrogram, most animal vocalizations were evaluated by ear. In the 1940s, technology to visualize sounds was developed in the military setting. This technology, called the Sona-Graph, became commercially available by the 1950s and has since revolutionized the science of human and animal communication (Marler 2004).

## A Guide to Understanding Spectrograms

In order to use spectrograms most effectively for studying bioacoustics, one must first understand the history of sound analysis. The biological world is full of sounds made by animals and the environment. The sounds vary in several dimensions (pitch, loudness, timbre, etc.) that can change over time. These separate components fit together, like a jigsaw puzzle, to create a perception of meaningful and complex auditory signals. Jean-Baptiste Joseph Fourier (1768–1830), best known for pioneering heat and vibration wave analysis, noticed that sounds were made up of complex waves (Fig. 1a), which were made of the combination of two or more simple sine waves (Fig. 1b). Just like puzzles can be deconstructed into individual pieces, complex sound waves can be deconstructed into their simple sine waves.

The deconstruction of a complex sound can be achieved through Fourier Transformations (FT). The FT is a mathematical technique for creating an instantaneous snippet of frequencies and amplitudes within a sound (Fig. 1c). This snippet is analogous to one puzzle piece. Today FT is performed automatically by the appropriate sound analysis program (e.g., Adobe Audition, Raven, Audacity, etc.), and no hand calculations are necessary. These programs use a Fast Fourier Transformation (FFT) algorithm, which is an efficient way to calculate and put together discrete FTs, on a time continuum. A spectrogram is a time-frequency visual representation of a sound that has been assembled, like a puzzle, by combining FTs together.

In order to perform FFT, sound in the environment has to be converted to a recording through a process of *sound digitization*. Modern technology permits novices and professionals to record sounds using every-day tools, such as cell-phones, or more sophisticated technology, such as recorders (e.g., Roland portable recorder, Tascam portable recorder). A digital audio recording is characterized by its *sampling rate* ( $F_s = 1/\Delta t$ ), or the number of times sound pressure is measured, and by *bit depth*, or the number of

**Sound Spectrogram, Fig. 1** (a) An example of a waveform graph of a complex sound with multiple frequency components (continuous line). Dots represent the waveform's digitized analogue. (b) 220 and 440 Hz pressure

sound waves that make up the complex sound wave in Fig. 1a. (c) A spectrum FT graph for the waveform in Fig. 1a with 220 and 440 Hz frequency components

bits of information in a sample. In order to have a reliable reproduction of the auditory signal, samples must be taken frequently (dots, Fig. 1a). This principle is known as the Nyquist Theorem. The highest frequency of a sound that equipment can digitize is the Nyquist frequency. In fact, a digitized sound can only honestly represent auditory frequencies that are half (or less) than that of sampling rate ( $F_s/2$ ). If this rule is not observed, the digitized sound, and subsequently the spectrogram, will be distorted, thus it is important to know the capacities of the recording equipment.

Once digitized, the sound can be analyzed to extract the frequency (a physical analogue of pitch perception), duration, amplitude (a physical analogue of loudness), and timing information. All of these components, or pieces of the puzzle, are necessary to generate a spectrogram. FFT assembles individual FTs together, creating a plot of frequency (y-axis) against time (x-axis), and

representing amplitude through color intensity, with darker colors indicating louder aspects of the vocalizations (Fig. 2). Thus, by visually and statistically examining the spectrograms, one can try to understand why the animal produces these sounds.

### Spectrograms in Modern Animal Bioacoustics

Animal bioacoustics is an interdisciplinary study area dedicated to understanding the acoustical world of animals. Recording and visualizing sounds (as in a spectrogram) provides a unique window into animal's life, allowing researchers to "see" the complexity of animal acoustic communication. Auditory signals have the benefit of traveling across long distances and are easier to detect in the environments with low visibility

**Sound Spectrogram, Fig. 2** A spectrogram of two mouse ultrasonic vocalizations. These vocalizations were recorded from a female mouse after being exposed to and separated from another female mouse. (This spectrogram was part of the Burke et al. 2018 project. It was reproduced with the permission of Dr. Micheal Dent)

(e.g., in the dark, under water, under ground, or in the forest) or when the animals cannot be visually located (e.g., humpback whales (*Megaptera novaeangliae*)). Spectrograms are widely used to study animal sound production and perception, the effect of environmental and man-made noise on animals in a variety of mediums, and to understand evolution and speciation of animals.

Some of the benefits of spectrograms are perhaps best understood by reviewing the notable examples in the scientific literature. In vocalization studies, a spectrogram can be used to count the number of vocalizations produced by an individual or several animals, and to categorize those vocalizations based on temporal (duration, frequency of occurrence, rate of production, etc.) and spectral (peak frequency, frequency range, bandwidth, etc.) characteristics. These measures can then be used to establish baselines for sex, age, and species-related vocal production. In isolated cases, it takes decades to truly understand the vocal abilities of certain animals even with the availability of spectrograms. For example, it was widely believed that female mice do not vocalize because no vocalizations occurred when a female

mouse was placed with an anesthetized male mouse (reviewed by Nyby 2001). Microphone arrays, careful experimental manipulations, and detailed spectrogram analyses now show that female mice vocalize in a variety of social and isolated situations (Burke et al. 2018).

Spectrograms have also contributed to the modeling of hearing and communicative disorders. In these studies, sound spectrograms can be altered by the researchers in order to determine what animal can and cannot hear. Operant conditioning (see ► “Operant Conditioning,” ► “Behaviorism”) procedures are frequently used for this purpose. In these studies, animals are trained to respond to a sound or a difference in sounds. Prior studies across species have utilized operant conditioning procedures to examine detection, discrimination, and identification of a variety of acoustic signals. For example, Kobrina and Dent (2016) showed that mice (*Mus musculus*) can detect vocalizations late into their lifespan, with male mice losing hearing at a faster rate than female mice. This pattern of age-related hearing loss is similar to those in humans, suggesting that mice can be used to model and investigate the basis of human age-related hearing loss.

Spectrograms have also been a useful tool in examining the effects of the acoustic environment and noise on vocal production, as well as establishing environmental standards for human activity (reviewed by Wiley 2015). One example is *frequency-shift adaptation* in noisy urban environments. Chickadee (*Parus atricapillus*) vocalizations are often masked by urban noise. To deal with this, chickadees decrease the duration and increase the overall frequency of their *fee-bee* song during peak auto traffic hours. This adaptation maximizes detectability of individual songs in low-frequency noise conditions (Proppe et al. 2011). While this species may adapt to noisy acoustical environments, not all species are capable of adapting to noise, and thus experience detrimental effects (Wiley 2015).

Spectrograms can also be used to understand the evolutionary development of acoustic communication in several species. For example, *spectrogram correlation analysis* is an objective quantitative measure of sound similarity that is

performed through analyzing several spectrograms, pixel-by-pixel. Researchers have used this procedure to study acoustic communication in toadfishes (*Batrachomoeus trispinosus*). Prior to *spectrotemporal correlation analysis*, it was unclear whether different toadfish species are acoustically distinct. Through the examination of typical vocalizations produced by toadfishes, Rice and Bass (2009) showed that *Batrachomoeus trispinosus* was vocally distinct from other toadfish species. This type of analysis shines light on how animals are capable of finding their conspecifics during mating without using visual, tactile, or chemical information.

## Conclusion

The spectrogram is a visual representation of sound that is assembled by combining multiple frequency and amplitude puzzle pieces. In order to use this tool, one must be able to digitize the sound and analyze it through a variety of software packages. These packages employ FFT analysis to create the frequency (y-axis) and time (x-axis) sound representation, with amplitude often expressed through color. The spectrogram is an important tool for studying animal auditory worlds and has significantly contributed to the study of animal bioacoustics. Spectrograms have been used to model human auditory perception, to study vocal repertoires of different species, to understand the effects of noise on animal welfare, and even to examine the acoustic evolution of species. Needless to say, spectrograms can be used in many other fields (medicine, engineering, etc.) and will continue to play a critical role in science and instrumentation progress.

## Sparse/Dense Discrimination

Michael J. Beran

Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

The sparse-dense discrimination task is a psychophysical judgment test used extensively in the area of assessing animal metacognitive abilities. The task involves two structural components. The first is the relative or absolute classification of stimuli as being sparsely or densely arranged. These are stimuli that consist of pixelated shapes (rectangles or circles) on a computer screen. The second component involves the presentation and potential use of the *uncertainty response*, which is a response that objectively operates to eliminate the requirement to make the primary discrimination and/or to provide an easier next trial or smaller reward. Its use has been interpreted to reflect metacognitive awareness on the part of subjects that use that response when they are at greatest risk of making an error of density judgment.

The first use of this task to assess metacognitive responding occurred with rhesus monkeys (Smith et al. 1997). In that task, monkeys were presented with a pixelated box on a computer screen, and they had to touch that box using a joystick-controlled cursor if it contained exactly 2,950 pixels. If it contained any fewer pixels, they had to classify it as sparse by selecting a large S on-screen. The third response option was the uncertainty response, which in that experiment provided the monkey the chance to avoid classifying the pixel box as sparse or dense and also guaranteed an easier next trial. Monkeys and adult humans engaged this task and provided strikingly

similar results. At the point at which both species showed objectively (through performance) that they could not tell whether the box contained 2,950 pixels or fewer, both species also showed the highest proportion use of the uncertainty response. This first experiment led to the claim that rhesus monkeys, like humans, monitored uncertainty and recognized difficult trials in a way that allowed them to “escape” those trials.

Subsequent experiments also tested humans and rhesus monkeys but with variations on the discrimination task. In one such study, subjects had to determine whether two boxes on-screen were equally sparse (or dense) in their pixelation or were different, or they could avoid making that response by choosing the uncertainty response (Shields et al. 1997). Again, these species performed highly similarly in avoiding the trials on which errors were most likely. In another test, monkeys first judged the density of a pixel box but then made a secondary confidence judgment that involved placing a low-risk, low-reward wager or high-risk, high-reward wager on that classification. Monkeys used a 2-level scale appropriately, although they could not use a 3-level scale (Shields et al. 2005).

In one of the strongest demonstrations of metacognitive monitoring by monkeys, Smith et al. (2006) trained monkeys to perform blocks of four successive trials of classifying pixelated boxes of varying density before they received any feedback as to how they performed. This meant that monkeys saw four stimuli in a row, classified each of those as dense or sparse, and then got feedback rearranged so that all rewards were delivered first and then all time-outs (for incorrect answers) were presented. Functionally, this made it very difficult to match specific responses to specific stimuli in terms of reinforcement or punishment outcomes. The question was how monkeys (and humans) used the uncertainty response in this case, and there was again high similarity across species. Most importantly, in some cases the monkeys’ pattern of responding showed that, under this deferred feedback, they mistakenly “centered” the sparse to dense continuum at the wrong place, and yet this is

also where they escaped the most trials. This showed that they escaped trials that they thought must be most difficult, even though those trials were not most difficult (i.e., the monkeys got more of these trials correct when classifying them than other stimuli that they answered often but escaped rarely). This dissociation of reinforcement structure and uncertainty responding was an important result for extending the case that monkeys engage in metacognitive monitoring (also see Couchman et al. 2010).

A later experiment also extended the demonstration of monkey metacognition using the sparse-dense task and a technique called cognitive loading. Smith et al. (2013) again gave rhesus monkeys pixelated boxes to classify as sparse or dense, but they also introduced a concurrent task that required the monkeys to retain in memory a stimulus for later recognition. When this concurrent cognitive load was present, monkeys’ ability to adaptively escape hard sparse-dense discrimination was negatively affected. However, cognitive load did not affect sparse and dense judgments themselves, nor did it affect monkeys’ ability to objectively classify stimuli as being in the middle density range. This demonstrated that uncertainty responses were uniquely affected by cognitive load, suggesting that these responses were executive-attentional responses rather than responses made under reinforcement-based stimulus control.

In another study (Zakrzewski et al. 2014), rhesus monkeys classified stimuli as sparse or dense, and correct responding led to increases in an on-screen collection of tokens that could be exchanged for food reward. However, errors erased the accumulated tokens and any possible rewards. Now, monkeys had to decide when to “cash out” their tokens and decide how certain they were about the density of a stimulus relative to how many tokens were at risk on that trial. As would be expected if uncertainty monitoring is flexible and responsive to things such as cost-benefit analyses during decision-making, the monkeys become more likely to escape a particular trial difficulty level if they had more tokens at risk on that trial. If they had few tokens at risk,

they made more classifications, even though the objective level of pixelation was the same in both cases. This result indicated that monkeys modulated their threshold for indicating uncertainty based on the stakes of the trial.

Not all species perform the dense-sparse task with equivalently proficient use of the uncertainty response. Capuchin monkeys (*Cebus apella*) have been presented with the two-response-class version of the task (calling a pixelated box either sparse or dense). Their perceptual acuity for denseness and sparseness matched that of rhesus monkeys, but capuchin monkeys only rarely integrated uncertainty responses into their performance. However, when given the chance to classify pixelated boxes in the middle of the stimuli continuum to the objective response class of middle, they did so proficiently (Beran et al. 2009). This outcome began a series of experiments to determine why capuchin monkeys may show less metacognitive monitoring and control relative to rhesus monkeys (and apes in other kinds of tests). In one such test, it was found that capuchin monkeys would not use an uncertainty response when faced with making sparse-dense discriminations even when all response classes were unrewarded, thereby making them equivalent in terms of positive reinforcement and punishment (Perdue et al. 2015).

The sparse-dense task has only been used with one non-primate species – pigeons. Sole et al. (2003) presented pigeons with pixels on a screen to be classified as sparse or dense. The pigeons did what monkeys and humans had: they opted out of exactly those trials they most likely to err on. However, other aspects of their behavior, such as performance on forced trials versus trials the pigeons opted to take, did not show differential performance, a result in contrast with human and nonhuman primate data and a result at odds with a strong claim of metacognitive ability. Thus, when applied across species, the sparse-dense task has had a substantial impact on understanding metacognition as it may emerge in other species and as it may operate in varied contexts of perceptual difficulty and risk.

The sparse-dense task also has been used in studies that tested humans exclusively. In one study (Paul et al. 2015), human participants classified a pixelated stimulus as sparse or dense while in an fMRI machine that monitored brain activity. Use of the uncertainty response was associated with a distributed network including prefrontal cortical (PFC), anterior and posterior cingulate cortex (ACC, PCC), anterior insula, and posterior parietal areas. Task difficulty was dissociated from these brain areas and their relation to uncertainty monitoring, and so this result also pointed to the uncertainty response as being more likely a declarative indication of uncertainty than a response tied to associatively learned reinforcement outcomes or punishments.

[Navigation](#); [Spatial abilities](#); [Spatial learning and memory](#); [Visuospatial memory](#)

## Definition

Spatial orientation refers to the ability of organisms to navigate. It is essential for their survival.

## Background

While navigating, we become familiar with an environment and acquire knowledge about it, thereby extracting information from it and storing this information in our memory so that we can recall it later for a variety of purposes (Ekstrom et al. 2018). Examples concerning rodents and humans will be presented since there is an important parallelism between them when dealing with spatial tasks. However, most of the examples will focus on how males and females differ when solving these tasks – on something that has recently been referred to as “qualitative” sex differences – thus counteracting the unjustified practice of ignoring females for so many years in psychological and biomedical research (for a review see Beery and Zucker 2011). To understand the sexually dimorphic spatial abilities between males and females – which are so influenced by sex hormones – a specific explanation, the range size hypothesis, will be discussed. For different reasons, this hypothesis applies to both rodents and humans. A brief description

of the role of the hippocampus while navigating and of the evolutionary origins of the human species is also presented. For navigational strategies and mechanisms used by rats see “► [Rodentia Navigation](#)” in the present issue (for the same in humans, see Ekstrom et al. 2018).

Although historically it has been assumed that sex differences do not exist or are not important beyond the reproductive system, this view has changed drastically in the last two decades. As it is widely recognized today a critical problem of ignoring females for so long has been the inability to understand the potential magnitude of the effect of sex on the outcome being measured, with the consequence of important problems in the reproducibility of basic research (Cahill 2006). No doubt research conclusions are needed that can be applicable to all. This requires sex as a biological variable “from womb to tomb.”

### **Sex Differences While Solving Spatial Problems**

Experiments on spatial learning and memory have shown that males and females of many mammalian species, including humans, often differ in their use of cues for spatial navigation (for reviews see Halpern 2012; Kimura 2000; Mackintosh 2011). It is not just that males tend to learn to solve a spatial problem faster than females, but that males and females can use different strategies to solve the same problem (i.e., this is what is considered a “qualitative” sex difference). In both rats and humans, males seem more likely to rely on geometrical information to reach a goal, while females are more likely to use landmarks.

Williams et al. (1990) showed that female rats have a clear tendency to use landmarks, such as specific objects and pictures on the walls, when solving spatial tasks, while male rats prefer geometric cues or sources of information, such as the shape of the testing room. Moreover Williams et al. found that if there were no landmarks available, the females used the geometric cues; however, males preferred to use the geometric cues, practically ignoring the landmarks. A similar difference in the preferred mode of solution has

been obtained with human participants, while using different navigational tasks (Sandstrom et al. 1998; Ward et al. 1986). For example, Ward et al. (1986) study how college students, males and females, give directions from maps – either perceptually available or committed to memory. Different aspects of direction giving were recorded. The results clearly revealed that when giving directions, women tend to use landmarks as points of reference, while men tend to use distance or cardinal directions (like North, South, East, and West). In the study by Sandstrom et al. (1998), male and female participants navigated through a virtual water maze where both landmarks and room geometry were available as distal cues. Manipulation of environmental characteristics revealed that females relied predominantly on landmark information, while males more readily used both landmark and geometric information.

Due to the important parallelisms between rats and people, recent research by Rodríguez et al. (2010) explored these “qualitative” sex differences in rats. The aim of the study by Rodríguez et al. (2010) was to evaluate whether there are differences in the way that males and females solve a simple but highly controlled spatial task in a modified Morris pool. In their Experiment 2, rats were trained in an unusual triangular-shaped pool to find a hidden platform, whose location was defined in terms of two sources of information: one landmark next to the platform, outside the pool, and one particular corner of the pool (see Fig. 1a, top-left). Three subsequent test trials without the platform were conducted. The first test trial pitted the two sources of information – landmark versus pool-shape – against one another (i.e., a preference test – see Fig. 1a, top-right). The results revealed that females spent more time searching the platform in an area of the pool next to the landmark, while males spent more time in the corner of the pool where the platform had originally been located (see Fig. 1b). In the following two tests the two sources of information were presented individually (i.e., learning tests – see Fig. 1a, bottom) and the results showed that both sexes had learned about both cues: males performed significantly better on the shape than

**Spatial Orientation,**

**Fig. 1** Experiment 2:

A schematic representation of the pool and the position of the landmark, X, as well as the hidden platform (*P*).

**b**

**c**

the landmark test, while females performed equally well on both. In addition, males spent more time searching for the platform in the target area on the shape test than females (see Fig. 1c). In conclusion, despite having clearly differentiated preferences, males and females process and can

use both geometric and nongeometric sources of information when they were presented together in the acquisition phase. Thus, this study shows a clear distinction between learning and performance, which was possible to gauge due to the different measures used in the three test trials.

A subsequent study by Rodríguez et al. (2011), where cue competition designs were used, confirmed the previous conclusion that shape (i.e., geometry) is clearly more salient for males, and landmarks somewhat more salient for females. Employing the same apparatus and general procedure as Rodríguez et al. (2010), this new study showed an asymmetrical overshadowing effect in both sexes. In males, shape overshadowed landmark learning, but landmark learning did not overshadow learning about shape; while in females, landmark learning overshadowed learning about shape, but shape learning did not overshadow landmark learning. It was the more discriminable, salient, or preferred source of information (shape or pool-geometry for males and landmark for females, as shown by Rodríguez et al. 2010) that overshadowed the less discriminable, salient, or preferred cue. The study by Rodríguez et al. (2011) helps to explain a frequently reported failure in the literature of landmarks to overshadow or block learning about geometry in male rats.

Importantly, in both studies (Rodríguez et al. 2010, Experiment 1; Rodríguez et al. 2011, Experiments 1 and 2a) the possibility that the estrus cycle of females could influence their performance was examined. It did not. There is one difference between the procedures used by Rodríguez et al. (2010, 2011) and those employed by Williams et al. (1990) that should be noted: in the experiments by Rodríguez et al. the landmark and the correct corner of the pool could be regarded as beacons which the rats learned to approach, whereas in the Williams et al. experiment the landmarks and shape of the room can hardly have acted as beacons. It is an open question whether this difference is important: but the parallel between these studies suggests that it may not be.

Taken together, all the data in the present section show that in the two species, rats and humans, adult males and females clearly differed in their preferred cues to solve navigation tasks. Importantly, a further study in rats by Rodríguez et al. (2013) with the same apparatus and general procedure as Rodríguez et al. (2010) revealed a different result when the rats were prepubertal.

Specifically, juvenile female rats behaved like males (both adult and juvenile), but unlike adult females, when searching for the platform in the preference test trial. This result reveals a change in the behavior of female rats as they grow older. Why is this? Based on the observation that ovariectomized females behaved like younger rather than older rats, Rodríguez et al. (2013) suggested that the obvious answer was that the hormonal changes associated with the onset of puberty changed the females' preference. That young female rats behave like males on a spatial task, while a sex difference appears only after puberty is consistent with the suggestion that sex differences in spatial cognition in humans appears due to the hormonal and cognitive changes associated with puberty (for a meta-analysis on this issue see Voyer et al. 1995).

### One Biological Explanation That Strengthens Over Time

A large number of hypotheses have been proposed to explain the qualitative, as well as other quantitative, sex differences often found in the spatial domain (for a review see Jones et al. 2003). Jones et al. (2003) concluded that the best predictor of the sex difference was range size, a biological hypothesis. This hypothesis is consistent with the argument that the differences found in males and females of many mammalian species are the result of some form of *natural selection*. Specifically, that both sexes have developed different strategies for spatial navigation and search due to a selective pressure of the environment, giving rise to different skills. In humans, the critical reason being that for a long time men hunted and women gathered. In other animals the most frequent explanation refers to polygyny, a mating system in which one male mates with several females in a single breeding season.

In agreement with the previous claim favoring males, in rats it has been found that different species of vole have a different range size between males and females depending on their mating system: males occupy a larger home range than females only if they are promiscuous, and not if

they are monogamous. When males occupy a larger home range than females, they also show superior spatial ability. The promiscuous male meadow vole is better than the female at several maze learning tasks (Gaulin et al. 1989), but in monogamous prairie and pine voles, there is no sex difference in maze tasks. The sex difference in meadow voles has also been observed in the Morris pool, which suggests that the result is strong in spite of using different tasks. Polygynous male deer mice are better than females at spatial learning, but again there is no sex difference in monogamous kangaroo rats (Jones et al. 2003).

Let's consider a pioneering study by Silverman and Eals (1992), which has expanded in humans the previous hypothesis, range size. According to these authors, the critical reason to explain the range size hypothesis is the division of labor that occurred in our earliest ancestors, where males were primarily hunters of mobile prey and females gatherers of immobile plant foods. Consequently, spatial abilities associated with hunting were naturally selected in males (and some typical tests that are currently used to measure these abilities include mental rotations, map reading, and different forms of maze learning); while spatial abilities related to gathering were naturally selected in females (and the measures suggested by Silverman and Eals include recognition and recall of spatial configurations of objects, as well as incidental learning for objects and their locations). They claim that our evolutionary history is thus responsible for different attributes in men and women when dealing with spatial tasks. A bias favoring men should be expected in those tasks reflecting abilities appropriated to hunting; while a bias favoring women should be expected in those tasks reflecting abilities appropriated to gathering. Therefore, sex differences in the spatial domain are expected to be task dependent. In their surprising work (Silverman and Eals 1992), they present a series of four studies that explore the hypothesized female spatial specializations by means of foraging scenarios. Briefly, in Study 1 – a pencil and paper test – university students of both sexes were asked to memorize the position of 27 objects

which were drawn on a sheet of paper. They had a minute to study the array. Following this, the sheet of paper was hidden and a new sheet of paper with some new items added was presented to the participants. They were asked to identify the new items in the second sheet of paper. The results showed that females were better at this task than males. Most importantly was the demonstration, in a third sheet of paper presented to the students, that females were also better when, instead of adding some new items to the initial array, the experimenters moved some of the items in the first sheet of paper to a different location – as shown in Fig. 2 – and the main task was to identify the moved items (i.e., a test of spatial or location memory). This better spatial memory score by females was not found if the participants were prepubertal (Study 4). Silverman and Eals (1992) emphasized that their results give clear support to the hypothesis that sex differences in the spatial domain are task dependent.

Two experimental field studies (Pacheco-Cobos et al. 2010; Vashro and Cashdan 2015) support the expanded range size hypothesis in humans. The work by Pacheco-Cobos et al. (2010) addresses the hypothesized female spatial specializations predicted by Silverman and Eals (1992). Specifically, the study focuses on the foraging techniques and success rate of Mexican men and women from a small village, San Isidro Buensuceso, as they searched for edible mushrooms on the slopes of La Malinche volcano, a region whose inhabitants have a long tradition of collecting mushrooms. The authors GPS tracked the foraging pathways of pairs of men and women from San Isidro Buensuceso while searching for mushrooms. Measures of costs, benefits and general search efficiency were analyzed and related to differences between the two sexes in foraging patterns. Although men and women collected similar quantities of mushrooms, men did so at significantly higher cost. They travelled further, to greater altitudes, and had higher mean heart rates and energy expenditure (kcal). They also collected fewer species and visited fewer collection sites. The authors conclude that in terms of search strategies developed for gathering wild mushrooms, and presumably other wild plants,

**Spatial Orientation, Fig. 2** Silverman and Eals' (1992) Object Location Memory task. Top: sheet of paper 1. Bottom: sheet of paper 3. (Reproduced with permission)

women outperform men. The women proved to be more efficient foragers than men in energy efficiency terms since they collected significantly more mushrooms while expending significantly less energy in doing so. These results provide the first support from a field study for the idea of a domain-specific spatiotemporal advantage for women in the type of foraging context that has probably been important for ancestral human females, as predicted by Silverman and Eals (1992). In agreement with the authors, similar studies are needed for other cultural groups, and for the gathering of different resources, such as firewood.

The study by Vashro and Cashdan (2015) focuses on the relationship between spatial-cognitive ability and range size in a population (the Twe and Tjimba of northwestern Namibia) that faces navigational challenges similar to those that faced many of our earliest ancestors, and tests the hypothesis that increased range size and better spatial ability confers fitness benefits (more mates and more children) for men. Data on range size, spatial ability, and reproductive success are combined in this study, in which the tasks employed were: mental rotation, water-level, object location memory task, pointing, range size measures, and reproductive history. The main results showed that Twe and Tjimba men have larger visiting ranges than women and are more accurate in both spatial (mental rotations) and navigational (accuracy pointing to distant locations) tasks. Men who performed better on the spatial task not only travelled farther than other men, but also had children with more women. Vashro and Cashdan (2015) argued that these findings offer strong support for the relationship between sex differences in spatial ability and ranging behavior, and identify male mating competition as a possible selective pressure shaping this pattern. The authors concluded that the benefits of increased mating range, increased hunting range, increased raiding ability, and women's preference to limit their range size may all have added to the selective pressure favoring sex differences in range size, navigation, and spatial cognition.

Taken together the main implication of the research in this section is that males and females

in the two species, rats and humans, have a very long evolutionary history which seems to be responsible, at least partly, of naturally "selecting" those traits of individuals that enhance their survival, giving rise to differential spatial abilities in the two sexes.

## **The Role of the Hippocampus in Spatial Learning and Memory**

The hippocampus plays a critical role in spatial learning and memory (Ekstrom et al. 2018; O'Keefe and Nadel 1978). Although hippocampal lesions do not impair rats' ability to swim to a visible platform in a Morris pool, such lesions have a drastic effect on their ability to swim to an invisible platform (Morris et al. 1982; Pearce et al. 1998). Morris et al. (1982) concluded that the performance of the task in which the rats had to learn about the location of a hidden platform in relation to distal cues is hippocampal-dependent but not the other kind of task in which the platform is visible, thus supporting the idea that the ability of navigation, which is essential for the survival of animals, depends critically on the integrity of this limbic structure. The following question has been repeatedly asked for many years. Is hippocampal volume different in the two sexes? The hippocampal complex (i.e., hippocampus and entorhinal cortex) is larger in male than in female rats, kangaroo rats, and polygynous species of voles (Kimura 2000). The importance of a sex difference in human hippocampal size is more controversial (McCarthy 2016). As Cahill (2006) has suggested, males and females of many mammalian species evolved under some similar, and some very different pressures. Thus, their brain organization would be expected to be both similar in some respects, and very different in others. This is precisely the situation found in the sex difference literature when dealing with spatial tasks.

There have been few studies that have used both sexes to understand the functional role of the hippocampal complex. For one exception see Roof et al. (1993). The Roof et al. (1993) study addressed working spatial memory in a Morris pool. They found that unilateral lesions of the

entorhinal cortex resulted in a differential performance in male and female rats. Specifically, males' performance was drastically impaired whereas females showed only a slight impairment, independently of the size of the lesion. These results already suggested that the role of both the hippocampus and entorhinal cortex in spatial learning seems to be different in males and females. Roof et al. (1993) ended their work by claiming that "Whatever the mechanism underlying the recovery or lack of impairment in females, it is clear from these results that more attention must be paid to the study of gender differences in determining or specifying structure-function relationships in the central nervous system. It is also clear that the issue of gender must be given more weight in planning and developing treatment and rehabilitation strategies for brain-damaged patients" (p. 50). Unfortunately, at present, most basic research in neuroscience is still conducted with males only.

In humans, a frequent way to understand the importance of the hippocampus while navigating has been to study London taxi drivers. Drivers of Black Cabs are not allowed to have satnavs, therefore they can only use their memory in order to navigate between more than 25,000 streets and thousands of places of interest. The exam to obtain permission to drive one of London's iconic *black cabs* is considered one of the most difficult in the world. It is known as "The Knowledge." At present, there are approximately 21,000 black cabs operating in London, although only around 2% of them are women. In a classic study conducted by Maguire et al. (2000), the relationship between spatial memory and grey matter in the hippocampus was studied in London taxi drivers. Maguire et al. (2000) found that grey matter in the hippocampus positively correlated with years of driving experience. Subsequent work by the same authors where more sophisticated techniques were used (such as functional magnetic resonance imaging – fMRI) replicated and expanded the previous results. Together these studies show that the hippocampus has an enormous flexibility and that the daily experiences we engage in can have an impact on it. This is also true when virtual tasks are used. For example, a

recent study by West et al. (2018) has provided the first evidence that activities such as action video games can reduce grey matter in the hippocampus and that this impact is mediated by a person's learning strategy. This is most important because low grey matter in the hippocampus is a risk factor for developing many neuropsychiatric illnesses. No doubt more work is needed in this fascinating line of research (West et al. 2018).

In conclusion, although currently it is well known that the hippocampus can be crucial when considering spatial tasks, recent research has revealed that other parts of the brain are also involved in these tasks, so that the main role of the hippocampus could be as an integrator "hub" in the brain (Ekstrom et al. 2018). Future work will have to deal with the many unanswered questions, including those related to sex differences.

### **Our Earliest Ancestors: Hunter-Gatherers Societies and Human Evolution**

Nomadism and the absence of private property are the two most important characteristics of the *hunter-gatherers* societies, in which men and women collaborated for subsistence. The understanding of the way of acting of those men and women is fundamental to understand the origin of humanity itself. Paleolithic societies are defined as nonproducers, acquiring their plant resources through harvesting, and animals through fishing, scavenging and hunting. This last one developed enormously during the Paleolithic, from being an opportunistic and indiscriminate hunting it become more specialized and the acquisition of resources, more diversified. Human hunting differs qualitatively from hunting by other animals. Unlike most animals, which either sit and wait to ambush prey or use stealth and pursuit techniques, human hunters used a wealth of information to make context-specific decisions, both during the search phase of hunting and when the prey has been caught (Clottes 2008; Fernández Martínez 2007; Kaplan et al. 2000). Hunter-gatherer societies lasted for over one hundred thousand years. This is much longer than all of recorded history.

Undoubtedly, our present predispositions must be a result of such a long period. Currently only a few such societies remain (such as the San Nyae Nyae Pam of Namibia, the Twe and Tjimba of North-western Namibia, or the Hadzabe in Northern Tanzania). These societies often constitute an authentic window to the past (like the study by Vashro and Cashdan 2015), thus complementing the information found at archaeological sites – the only direct testimonies that have reached us until today.

Since our split from the chimpanzee lineage, the human evolutionary branch underwent many great changes, like an increase in brain size with respect to the rest of the body, smaller teeth, bipedalism, great manual dexterity, the ability to make and use tools, satnavs, etc. Our evolutionary story is not linear. Rather, like other animals, the human family tree is much more like a bush made up of a variety of “adaptive radiations” in response to changing environmental circumstances (Fernández Martínez 2007). A frequently asked question in the literature among anthropologists is how was the labor collaboration between men and women done? Here are two opinions of experts. In his beautiful book addressed to his grandchildren Clottes (2008) says “the men, physically stronger, were engaged in hunting. While the women, who took care of the children and accompanied the older members of the family clan, had the mission of collecting all kinds of edible wild fruits and locating dead animals from which meat could be used” (pp. 43–44). According to Kaplan et al. (2000), “human pair bonding and male parental investment is the result of complementarity between males and females. The commitment to caring for and carrying vulnerable young, common to primate females in general, together with the long period required to learn human hunting strategies, renders hunting unprofitable for women” (p. 173). Several reasons have been used to explain this division of labor. Men are, in general, taller than women and they are also more muscular. Thus, women tend to have less physical strength than men, and a lot of physical power is required to throw spears and missile weapons at large-game. In addition, women are more valuable than men because they

have children. The group survival depended on women and, therefore, it was important for the group to avoid their implication in situations of great danger. The differences between men and women are largely due to different hormonal actions during development (i.e., testosterone production in men and estrogen production in women). Contrary to what was believed for a long time (Kaplan et al. 2000) recent research has shown that collecting mushrooms, wild fruits, and edible plants (activities that women and children mainly did) constituted up to 60–70% of the food. Nowadays it is considered that these activities were more important in the long term than that of large-game hunters for the survival of the group (Clottes 2008; Fernández Martínez 2007; Mackintosh 2011). From the perspective of human evolution, the gender-specific tasks (i.e., men primarily hunters, while women primarily gatherers) are an excellent example of cooperation between men and women due to a selective pressure of the environment to solve adaptative problems, ultimately to ensure the perpetuation of the human species.

In conclusion, as we saw in section “[One Biological Explanation That Strengthens Over Time](#),” evolution by natural selection seems to have been the process of adapting human males and females attributes to best function in their environment. The spatial domain is not an exception. A sensible view would be to consider that males should not be regarded as more highly spatially specialized than females, but differently specialized, as claimed by Silverman and Eals (1992). If we refer to the ability to navigate in large spaces, men tend to have a better performance than women. On the contrary, if we refer to the ability to navigate in small spaces, the opposite is usually frequent and women tend to have a better performance than men.

## Final Conclusions

At present, it is well known that the brain has a great plasticity and that activities we engage in during our daily lives have a direct impact on it. For example it has been shown (West et al.

2018) that 90 h of action video games can shrink the hippocampus. Considering this evidence, what could we expect after ten millennia of the division of labor? This is an open question waiting for clear answers. At least different predispositions to attend to various sources of spatial information could be expected due to our evolutionary history. No doubt, cognitive intervention programs at schools (for example, different types of games – geometric for girls and spatial memory ones for boys) could help to reduce the sex differences observed in adulthood. Furthermore, it is quite remarkable that young baby boys and baby girls differ when mental rotation tasks with 3D objects are used (Lauer et al. 2015; Moore and Johnson 2008). These results reveal clear sex differences in the spatial domain long before puberty which are difficult to explain, thus weakening the apparent parallel between rats and humans. Future research will have to deal with the very many unanswered questions.

A final thought refers to technology. Is it really good for us? Are not we atrophying our grey matter in the hippocampus with so much dependence on satnavs or GPS for example? Following GPS indications resembles a route following task, where a specific part of the striatum, the caudate nucleus, can be very active. Recent research has shown (for a review see Ekstrom et al. 2018) that the caudate nucleus shares an inverse relationship with the hippocampus, in both humans and rodents (i.e., increased grey matter in one structure is correlated with decreased grey matter in the other). Consequently, with so much dependence on technology, we could be impoverishing ourselves as a species. This worrisome situation should be taken more into account in the new spatial habits we are acquiring.

## Synonyms

[Egg deposition](#); [Egg release](#); [Reproduction](#)

## Definition

The act of gamete release in aquatic environments.

## Introduction

Spawning refers to the process of depositing the gametes into the water. It is thus a characteristic of “ovuliparous” organisms in which eggs are fertilized by sperm externally. The vast majority of anamniotes (fish and amphibians) and aquatic invertebrates reproduce in this way. Aquatic species in which there is internal fertilization and where the females lay zygotes (zygoparity) and early embryos (embryoparity) or where the young are born alive (viviparity) are not considered spawners. On the other hand, the deposition of gametes in moist terrestrial habitats such as the emergent leaves of aquatic plants (e.g., the characin *Copeina arnoldi*) or on beaches above the breaking waves of the open coast (e.g., the

California grunion, *Leuresthes tenuis*) should be considered as spawning (terrestrial and beach spawning, respectively).

## Spawning Site Selection

Spawning methods are diverse. Broadcast-pelagic spawners (pelagophils) shed their gametes in staggeringly large quantities into the water where they are mixed in clouds and fertilization occurs. One of the most spectacular spawning events to occur on aquatic ecosystems is the mass reproduction of corals simultaneously releasing tiny egg and sperm bundles from their polyps into the water. This is the point where parental contribution ends and the fertilized eggs are simply left to the mercy of the perilous aquatic world where predators, starvation, and adverse environmental conditions will only allow a small fraction to survive and be recruited into the population. This *r*-selected strategy seems suitable for the unstable and unpredictable oceanic environment, which explains why most marine organisms, regardless of their ocean-neritic or pelagic-benthic distribution, produce pelagic eggs. The pelagic zone can host vast amounts of spawn, while food particles – especially in the euphotic zone – are readily available and in abundance for the first-feeding larvae. In addition, pelagic embryos have improved chances to expand the distributional coverage of marine populations through passive movement. Eggs of marine fishes are usually smaller (about 1.0 mm in diameter) and almost always buoyant and liberated into the pelagic zone.

In freshwater environments the share of food in the water column is not as abundant as in the pelagic environment, and due to low salinity, fertilized eggs do not float as easily. Also, the embryos that are deposited in the column – especially in rivers and streams – are in danger of being dragged by raging waters far from their parental habitat or even transported to the sea. Therefore, freshwater organisms usually produce eggs attached to the substrate, vegetation, or even nests built by their parents who then exhibit higher rates of parental care. Ovuliparous amphibians such as frogs lay a gelatinous mass of eggs (frogspawn) in ponds and

ditches. Freshwater fish eggs are more likely to be larger (1.0–2.0 mm in diameter) and to be attached to weed or stones, and some are laid in nests or brooded in various ways. Such patterns have been known to humans for thousands of years. Aristotle gave a precise description of the process of spawning for some freshwater fish such as *Silurus glanis* (also known as Aristotle's catfish) which “deposits its spawn in a continuous string, as frogs do; so twisted is this fetation and so even that fishermen in the marshes can unwind it off the reeds like thread” (Ganias and Voultsiadou 2017).

## Exceptional Patterns

Variations to the above general rules can be encountered in both marine and freshwater organisms. For example, even if parental behavior is more common in freshwater than in marine fish (Baylis 1981), some littoral species of bullheads (Cottidae), blennies (Blenniidae), and gobies (Gobiidae) protect their eggs which are simply attached to the substratum (Bone et al. 1997). Although nonfloating kind of eggs may be best suited to freshwater, there are a few species, such as gouramis and grass carp, who produce buoyant eggs (Bone et al. 1997). On the other hand, although marine eggs are almost always buoyant and liberated into the pelagic zone, herring (*Clupea harengus*) and capelin (*Mallotus villosus*) are exceptions, laying sticky demersal eggs that adhere to weed or gravel on the sea bed or in the intertidal zone.

## What Makes an Egg Buoyant?

Egg size in pelagophil fishes is exceptional in that apart from the optimization of offspring quality and size it also reflects the egg volume adjustment that is necessary to counterbalance heavy chorion material in order for the egg to be buoyant. This adjustment is mainly achieved by increasing the aqueous content of the egg through a sequence of events that occur both in utero, at the oocyte stage, and after ovulation and spawning, at the egg stage (Jung et al. 2014).

However, most of the water uptake occurs during the reinitiation of meiosis (final oocyte maturation), before ovulation, a process known as “oocyte hydration” (Thorsen and Fyhn 1996). This process renders the eggs and early embryos buoyant in the seawater, allowing their survival and dispersal in the ocean. In both marine and freshwater pelagophils, one or more oil globules, which are greatly oversized in some freshwater species, form an additional hydrostatic organ.

## How the Eggs Meet with Sperm in the Wild

The likelihood that eggs and sperm will meet in the water is increased through various eco-ethological adaptations such as the interaction of the sexes and the formation of spawning aggregations. Females and males seem to synchronize ovulation and milt production and communicate through chemical signals called pheromones. Sorensen et al. (2004) suggested that the maturation-inducing steroid, 17,20bP, and its sulfated metabolite, 17,20bP-S, are the primary components of the preovulatory pheromone, which affects male fish, acting through specific olfactory receptors. The haddock (*Melanogrammus aeglefinus*), for example, goes through quite an elaborate courtship involving visual displays by the male and vocalization (Hawkins and Amorim 2000). In many fish species, even in pelagic spawners, males and females interact often on a one-to-one basis.

Spawning aggregations are groups of conspecifics gathered for the purpose of spawning with densities or numbers significantly higher than those found in the area of the aggregation during nonreproductive periods. Spawning aggregations may be resident or transient and are usually spatially predictable, found at sites in association with particular physical characteristics. Their formation can also be predictable in time, occurring in phase with circadian rhythms, at seasonal, lunar, diel, or tidal periodicities. Most published information on spawning aggregations refers to teleost fishes, a smaller number of publications refer to invertebrate species (mostly cephalopods), and only few publications refer to sharks

and other vertebrate organisms. The formation of spawning aggregations is quite usual in coral reef fishes such as the groupers (Serranidae) and the snappers (Lutjanidae) (Claydon 2004). However, other fish such as the benthopelagic gadoids, especially the cod, *Gadus morhua*, also form spawning aggregations. Spawning aggregations are postulated to reduce predation on both adults and their offspring, to increase mating success and fertilization rate, and to help regulate the sex ratio in some populations.

### Cladogenesis

## Definition

The process of formation of new species during the course of evolution is called speciation. It occurs when a group within a species separates from the other members of the group and develops its own characteristics. Therefore, speciation involves the splitting of a single evolutionary lineage into two or more genetically independent lineages. This differentiation into the new species is dictated by the evolutionary factors (National Geographic 2011).

The rate at which the diversification of the species is taking place can be understood roughly by assuming that there are  $\sim 10^7$  different species on earth, if bacteria and archaea are not accounted for (Mora et al. 2011), and life originated on earth singly  $\sim 4 \times 10^9$  years ago. These estimates indicate that the average diversification rate can be calculated as 0.0025, meaning that one new species is formed every 400 years. This is an underestimate, primarily because it does not account for extinction events or bursts of speciation and secondarily because microbes are undercounted. Moreover, an important point to be mentioned is the presence of the intermediate forms, which emphasizes the fact that speciation is a continuous process (Mallet 2008).

An important example of speciation is that of Galápagos finches. The Galápagos archipelago,

located in the Pacific Ocean off South America, is a host to many species of finches. Each species is on an island, separated from each other geographically by means of the ocean. Therefore, over a period of 2–3 million years (Grant and Grant 2011), each species of the finch has developed unique beaks that are especially adapted to the specific food available on each island. The food available to them is widely different due to their presence on different islands separated by oceans. The beaks range from being large and blunt for breaking into hard nuts to long and thin for probing into cactus flowers (Abzhanov 2010).

## Modes of Speciation

As has already been described, speciation, or cladogenesis, is the process in which one population lineage splits into two or more distinct lineages. This process is fundamentally different from anagenesis, in which an interbreeding population gradually changes over time until it reaches a point where it becomes sufficiently distinct from its ancestors (Emerson and Patiño 2018). Four modes of speciation have been generally described in literature:

### Allopatric Speciation

Allopatric speciation is the speciation that occurs when a population is split into two due to geographical isolation, for instance, formation of a mountain or separation due to an ocean, as in case of the Galápagos Islands finches. Another example is that of the squirrel population in Arizona's Grand Canyon. Before the formation of this canyon, only one population of the squirrel existed, but, after the formation of this geographical barrier, that squirrels could not cross, they were split into two populations due to the absence of interbreeding. As a result, currently, the north and south rims of the canyon have genetically distinct squirrel populations. Contrary to this, the birds could easily cross through this barrier and continued to interbreed, and no splitting of the population occurred in this case (National Geographic 2011; Abzhanov 2010).

### Peripatric Speciation

Peripatric speciation occurs when a small subset of a population buds off from the parent population and forms a new species. The major difference between the allopatric and peripatric speciation is that, in the latter, one group is much smaller in size as compared to the other. Due to the small size of the population, the unique characteristics of the population are easily passed on and become more common in the future populations, thus distinguishing them from the others (Dunn 1989).

### Parapatric Speciation

The most defining feature of parapatric speciation is that the species are spread over a large geographical area. While not geographically divided, because of distance, interbreeding occurs only among the individuals of a species of a given geographical region. An example of this type of speciation is the buffalo grass growing in the areas polluted by metals. Although this metal-tolerant grass is not geographically divided from the buffalo grass growing in the other areas, long distance makes it impractical to reproduce with the other members of the species (Understanding Evolution. University of California Museum of Paleontology 2019).

### Sympatric Speciation

When two or more species form diverge from a parent species and live in the same geographical area, the process is called sympatric speciation. In addition to living in close proximity, there are also no physical barriers occurring between the interbreeding members of a species, yet a new species arises, for example, based on a change in food availability. An example of sympatric speciation is the apple maggot. This species diverged from the one which lays eggs in hawthorn and started laying eggs in apple after the introduction of apple trees in to North America. However, the parent hawthorn species still exists, and populations of both species overlap (Coyne 2007).

### Conclusion

According to biological species concept, a species is a group of individuals belonging to one or more populations that have the ability to interbreed and produce healthy and fertile offspring. However, in speciation, evolution of genetic differences occurs as a result of reduced gene flow. This can be attributed to the prezygotic and postzygotic barriers, acting before and after the formation of zygote, respectively, which prevent the species from mating and thus cause the reproductive isolation of the species.

University of California, Davis, CA, USA

### The Concept of Species and Its definition: An Historical Perspective

Species are the fundamental units of biological classifications. Understanding the concept of species is important both because species are the units of comparison across different biological disciplines including behavior, evolution, genetics, ecology, anatomy, development, and molecular biology, and because it plays an important role for the formulation of environmental law and ecological conservation. Species are also the currency by which biologists measure biodiversity. However, biologists largely disagree on the definition of “species.”

Attempts to define the concept of species date back to the Greek philosophers Plato and Aristotle, who viewed the world as we know it as a flawed shadow of the eternal and immutable world of ideas. Indeed, the word “species” originates from the Latin “kinds” which is a translation of the Greek word *eidos* (idea). According to this view, the world we live in is imperfect and variable and it is only a projection of the ideas that are real and unchanging.

However, it was an English naturalist, John Ray (1628–1705), who introduced for the first time the concept of “species” in biology. In his 1686 *Historia Plantarum* he wrote:

In order that an inventory of plants may be begun and a classification of them correctly established, we must try to discover criteria of some sort for distinguishing what are called ‘species’. After a long and considerable investigation, no surer criterion for determining species has occurred to me than distinguishing features that perpetuate themselves in propagation from seed. (quoted in Briggs and Walters 2016, p. 4)

In other words, according to Ray, species are those groups of organisms that resemble their

parents. Although Ray acknowledged that there can be some variants or “accidents” – as he called them – within a species, such as different heights, scents, or colors, organisms that differ by these characteristics should not be considered as different species. Ray, also, tried to reconcile the idea of “species” with the Bible account of Creation, and believed that all species were created at the same time and no new species could come into existence. While Ray is regarded as the first person who introduced the concept of species in biological terms, Carl Linnaeus (Carl von Linné, 1707–1778) is considered the true father of modern biological taxonomy and classification. In his *Systema Naturae* (first edition 1735), Linnaeus formulated a system to classify organisms, by identifying five categories: kingdom, class, order, genus, and species. Before Linnaeus, the classification of organisms was somewhat arbitrary, and organisms were often given long names that could be easily altered, making it more difficult for different biologists to understand what species they were referring to. Linnaeus was the first one to formulate the classification based on organism similarities, and to designate the binomial system (*genus* + *species*) to classify organisms. Interestingly, in the first editions, Linnaeus still considered species as fixed, a view that emerges also in other publications. In *Critica Botanica* (1737), for example, he defended the concept of fixity of species:

All species reckon the origin of their stock in the first instance from the veritable hand of the Almighty Creator: for the Author of Nature, when He created species, imposed on his Creations an eternal law of reproduction and multiplication within the limits of their proper kinds. He did indeed in many instances allow them the power of sporting in their outward appearance, but never that of passing from one species to another. (quoted in Briggs and Walters 2016, p. 6)

Over the years, however, Linnaeus’s observations led him to realize that species are not immutable entities as different species of organisms cannot always be easy to distinguish, and in his tenth edition of *Systema Naturae* he acknowledged that new species of organisms can be formed through intergeneric crosses. He even wrote a document, *Plantae Hybridae* (1751), where he listed

100 plants that might have been considered as hybrids.

One of the most influential figures in human history, because of his theory of evolution by natural selection, is undoubtedly Charles Darwin (1809–1882), author of the *On the Origin of Species* (first edition: 1859). There is still large debate on Darwin's concept of species, mainly because of largely contradicting statements that emerged from his book. In some cases, Darwin (1859) appears to consider the concept of “species” as a human construct: in p. 52 he wrote:

I look at the term species, as one arbitrarily given for the sake of convenience to a set of individuals closely resembling each other, and that it does not essentially differ from the term variety, which is given to less distinct and more fluctuating forms.

While in a letter dated 1860, he wrote:

How absurd that logical quibble—“if species do not exist how can they vary?” As if any one doubted their temporary existence?

The current view that tries to reconcile these apparently contradicting opinions Darwin held on the concept of species is that Darwin did believe that the specific species taxa exist, but he questioned the existence of the “species” category, given that, according to Darwin, there cannot be a clear boundary between species and variety. In other words, the variation that distinguishes each set of individuals is so continuous that setting the boundaries to attribute to these different populations the rank of species appears to be more a convention than a reality. This view sets Darwin's approach apart from earlier naturalists' idea that each species was produced in the current form by a Creator, with only little variation between individuals belonging to the same species.

## Current Concepts of Species

A high number of species concepts has been developed over the years: Wilkins (2006) identified a total of 26 definitions of species, while Zachos (2016), more recently, counted 32 species concepts. According to Wilkins (2006), only

seven of these concepts are really independent: *morphological, biological, evolutionary, genetic, taxonomic, ecological, and agamospecies concepts* and, as Wilkins himself pointed out, some of these concepts are not definitions of what species are, but how biologists can identify them. In other words, most of these concepts do not question whether species are concrete describable objects in nature, but how best to define this class of objects so that any other object that possesses attributes that do not belong to this class of object can be excluded. Here some main species concepts, namely the morphological, biological, evolutionary, genetic, ecological, and agamospecies, will be discussed, while a complete and recent list of all the concepts can be found in Zachos (2016).

### Morphological Species Concept

Under the Morphological Species Concept, Cronquist (1978) defined the species as “the smallest groups that are consistently and persistently distinct, and distinguishable by ordinary means” (quoted in Wilkins 2009, p. 214). According to this concept, the species can be distinguished on the basis of their morphological features. This approach is also called *essentialist*, as, under this view, members of a species can be identified by their essential characteristics, or *typological* since it posits that all the diversities on earth reflect a limited number of “types.” While this concept dates back to Aristotle and Plato's concept of “ideas” and was adopted by Linnaeus and other earlier naturalists to classify the organisms, this view has been largely abandoned on the ground that individuals belonging to the same species can display large intraspecific differences, because of marked sexual dimorphism, aging, or polymorphism or perfectly distinct species can be morphologically similar to each other (the-so called cryptic species).

### The Biological Species Concept

The Biological Species Concept is probably one of the most cited definitions of species. It was first defined by Dobzhansky (1935) as follows:

A species is a group of individuals fully fertile inter se, but barred from interbreeding with other similar groups by its physiological properties (producing either incompatibility of parents or sterility of the hybrids, or both)

This definition was then expanded by Mayr (1940) who originally defined species as

A group of populations which replace each other geographically or ecologically and of which the neighboring ones inter-grade or interbreed wherever they are in contact or which are potentially capable of doing so (with one or more of the populations) in those cases where contact is prevented by geographical or ecological barriers.

In other words, species are groups of individuals who interbreed but who are reproductively isolated from other groups. Mayr (1969) defined a species as both a *reproductive unit*, in which members seek each other to reproduce, an *ecological unit*, as individuals of a species share the same environment, and a *genetic unit*, whose members share the same set of genetic information. There are two main mechanisms by which reproductive isolation can be achieved: *pre-zygotic* and *post-zygotic*. Pre-zygotic isolation includes:

- *Ecological isolation*: when different populations occupy different geographical areas or different ecological niches.
- *Behavioral isolation*: when different populations display different behaviors that prevent them from interbreeding, such as different courtship rituals, mating calls, or chemical signals.
- *Temporal isolation*: when different populations produce gametes at different times. This is particularly common in plants that exhibit different flowering periods.
- *Mechanical isolation*: when females and males have reproductive organs that are compatible only among members of their own species. This type of reproductive isolation is particularly common in insects.

Post-zygotic isolation includes:

- *Hybrid viability*: when the hybrid dies prematurely

- *Hybrid infertility*: when the offspring that is produced by the two different species is infertile

There are a number of problems with the Biological Species Concept:

1. Mayr's biological concept definition can only apply to sexual organisms but it does not work for those organisms who do not reproduce sexually, such as protozoans.
2. The biological species concept can only be applied to the species that share the same space at the same time, making the definition inapplicable to species that live at different times (i.e., fossils) or in different geographic regions. This is because it is hard to test whether two populations that live at different times or in different areas can reproduce. In p. 121 Mayr (1940) states that: "the application of a biological species definition is possible only in well-studied taxonomic groups, since it is based on a rather exact knowledge of geographical distribution and on the certainty of the absence of interbreeding with other similar species." To address this issue, Mayr (1970) took out the word "potentially" by the Biological Species Concept and defined species "as those groups of interbreeding natural populations that are reproductively isolated from other groups" (p. 12).
3. Finally, there is a plethora of cases in which interbreeding between different species results in fertile offspring. Some *genera* are renowned for including species that have a high ability to interbreed, such as the genera *Cervus*, *Lepus*, *Canis*, and *Macaca*. Hybridization appears to be particularly common in birds: Grant and Grant (1992) calculated that about 1 in 10 species of birds are known to have bred in nature with another species. Mayr (1970) tried to solve the problem of hybridization by revising his definition of "isolating mechanism" to "biological properties of individuals which prevent the interbreeding [fusion] of populations" (p. 56). In other words, these isolating mechanisms would not be able to guarantee the complete lack of interbreeding

between different species, but it would prevent the complete fusion between them.

### The Evolutionary Species Concept

The Evolutionary Species Concept tried to solve the nondimensional nature of the Biological Species concept by defining species as “a lineage (an ancestral-descendant sequence of populations) evolving separately from others and with its own evolutionary role and tendencies” (Simpson 1961, p. 153). The second part of the definition (“own evolutionary role and tendencies”) is particularly important as it implies that there should be some sort of biological relevance when assigning a group of individuals the status of species, and it precludes considering species from any ephemeral offshoot of the species, such as small captive populations. The main criticism is that this concept is not an operational definition as it does not help to identify whether a specific class of individuals belongs to a specific species. Furthermore, from the definition of Evolutionary Species Concept, it is unclear which level of lineages we should consider the species level, as lineages exist at different levels. Wiley and Mayden (2000) solved this issue by identifying evolutionary species as those tokogenetic entities “composed by parts (individual organisms) linked by reproduction and manifested by tokogeny” (p. 74) where tokogeny is defined as the biological relationship between parents and offspring or, more generally, between ancestors and descendants.

### The Genetic Species Concept

Baker and Bradley (2006) defined a genetic species as a “group of genetically compatible interbreeding natural populations that is genetically isolated from other such groups.” While the core aspect of the Biological Species Concept is reproductive isolation, the key element at the basis of the Genetic Species Concept is *genetic* isolation, produced by an accumulation of genetic changes. The initial criticisms against this concept is that it would be hard to accurately estimate genetic distance, especially considering our lack of knowledge of an organism’s genetic information. However, recent genetic advances have made it

possible to assess genetic differences between organisms. For example, an examination of the variation in mitochondrial cytochrome-*b* gene sequence across several mammalian species suggests that genetic distance values lower than 2% indicate intraspecific variation (hence the organisms belong to the same species), values >11% represent different species, while values that range between 2% and 11% deserve further investigation in order to understand whether they should be considered the same or different species (Bradley and Baker 2001). The important difference between the Genetic and Biological Species Concepts is that while the former considers populations as distinct species even if there is gene flow and their hybridization produces fertile offspring, the Biological Species Concept would recognize these two populations as the same species (and different subspecies). There are numerous examples in nature of populations that might appear to belong to the same species, but genetic analyses reveal as different species, and Baker and Bradley (2006) estimate that there are more than 2000 unrecognized species.

### The Ecological Species Concept

The Ecological Species Concept was introduced by Van Valen (1976), under the idea that differences in ecological niches, more than genes, are the primary drivers of evolution and that reproductive isolation plays a minor role in the formation of the species.

Van Valen (1976) defined species as “a lineage (or a closely related set of lineages) which occupies an adaptive zone minimally different from that of any other lineage in its range and which evolves separately from all lineages outside its range.” According to Van Valen (1976), an adaptive zone is considered the part of the environment that contains a specific set of resources along with certain levels of predation and parasitism, and can have boundaries that are either pre-existing or defined by the species that are living there. Under this concept, populations that live in separate areas can still be considered as belonging to the same species if they are under the same ecological pressures. Grant (1992) pointed out that the idea that ecological adaptations play an

important role for the formation of species is not new and even the “fathers” of the Biological Species Concept acknowledged the importance of ecological factors. In the *Genetics and the Origin of Species* Dobzhansky (1951), for instance, highlighted how the phenotypic and genetic discontinuities between species are probably related to differences in their ecological niches, and that reproductive isolation manages to fix these phenotypic and genetic differences. The main criticism of the Ecological Species Concept, however, is that we cannot have a priori knowledge of what makes an ecological niche and, in fact, researchers often use ecological differences between species to characterize their ecological niches (Grant 1992). Furthermore, in many species, different morphs or different sexes can occupy different niches and so we cannot reliably use ecological differentiation as a diagnostic of a species.

### The Agamospecies Concept

Many of the abovementioned concepts do not apply to organisms who do not reproduce sexually and who lack genetic exchange. This is because the key aspects of the Biological and Genetic Species Concepts are reproductive and genetic isolation, respectively, and Wiley and Mayden (2000) had to drop the word “population” from their definition of Evolutionary Species Concept in order to be able to include asexual organisms. The first definition of agamospecies concept was given by Turesson (1929), who defined species as “an apomict-population the constituents of which, for morphological, cytological or other reasons, are to be considered as having a common origin” (quoted in Zachos 2016, p. 98). This definition can be considered as a “Morphological Species Concept” applied to asexual organisms. Another definition was provided by Cain (1954) who defined agamospecies as “those forms to which [the biological species concept] cannot apply because they have no true sexual reproduction.” The problem with this definition is that it defines the “species” as *not being* something else. A better definition, which was originally used to define viruses, was given by Eigen (1993), who coined the term *quasispecies*, defined as “a self-sustaining population of sequences that reproduce

themselves imperfectly but well enough to retain a collective identity over time.” The concept of quasispecies hinges on the observation that in a cluster of genotypes of viruses there is an optimal (or wild) type with specific mutations that make it particularly adapted to a specific environment, from which other viruses reproduce. This definition is very similar to the *Ecological Species Concept* and can be applied more generally to asexual organisms, which is why Wilkins (2009) considers *agamospecies* and *quasispecies* synonyms.

### Modes of Speciation

Speciation (or *cladogenesis*) is the biological process by which species originates from the ultimately irreversible splitting of one population lineage in two or more lineages. Importantly, this evolutionary process is different from the *anagenesis* that occurs when a population lineage gradually changes over time until it reaches the point when it becomes sufficiently distinct from its ancestor. There are three main modes of speciation: *allopatric*, *sympatric*, and *parapatric*.

- *Allopatric (or geographic) speciation* is the most common form of speciation and occurs when different populations from the same species become isolated and no genetic exchange occurs between them. These isolated populations undergo genetic changes over time due to mutations, migration, or other evolutionary forces, to the extent that they become reproductively isolated from each other. There are two main forms of allopatric speciation: *dichopatric* and *peripatric*. Dichopatric speciation arises when populations inhabiting a specific geographic area become isolated due to the development of a new geographic barrier that splits the original population into two or more groups. Peripatric speciation occurs when a single gravid female or few individuals of a species colonize a new geographic area. This, in turn, results in *genetic drift* and *bottleneck effects* that lead to genetic changes and reproductive isolation from the original species. Classic examples of allopatric speciation

are Darwin's Galapagos finches: these are 15 species of birds inhabiting different islands on the Galapagos archipelagos, located in the Pacific Ocean off South America. Over millions of years, these bird species have evolved different types of beaks of different size and shape that are particularly adapted to the type of food they eat (Abzhanov 2010). For example, ground finches, like *Geospiza magnirostris*, *G. fortis*, and *G. fuliginosa*, have stout beaks for eating seeds, while cactus finches, such as *G. conirostris*, have longer more pointed beaks to feed on nectar or getting seeds from cacti (Fig. 1).

- *Sympatric speciation* occurs when a new species originates in the same geographic area of the parental population. It is less common than allopatric speciation and can occur, for instance, when part of the population starts using a new niche, and is more likely to occur in herbivorous insects that display a particularly specialized relationship with their host plants. A textbook example of sympatric speciation is the apple maggot *Rhagoletis pomonella*: apple maggots used to lay their eggs exclusively in hawthorns, which are native to America. However, 200 years ago, they started using also domestic apples, which were introduced to America by immigrants. Since males generally look for mates on the type of fruit they grew up in and females lay their eggs on the type of fruit they grew up in, hawthorn flies generally mate with hawthorn flies and apple flies mate with apple flies preventing gene flow between the two types of flies and providing the first step for sympatric speciation.
- *Parapatric speciation* occurs when individuals from a continuous population tend to mate with geographic neighbors more often than with individuals belonging to other areas of the population's range due to differences in the same environment. These local populations are called *demes*. Different demes of a population are not isolated from each other, as individuals can move from a deme to the other but given that individuals tend to mate only with members of their own demes, they might be

subject to specific selective pressures that can lead them to become a whole new species. A species who might be undergoing parapatric speciation is *Anthoxanthum odoratum*. This plant species grows in mining zones, whose soil is contaminated with high levels of heavy metals, and members of this species have developed a high tolerance for heavy metal. Although these tolerant individuals live close to the same species of plants that do not grow in contaminated ground, tolerant and non-tolerant plants have developed different flowering times. This temporal isolation indicates that tolerant individuals would breed only with tolerant individuals and nontolerant individuals would reproduce only with nontolerant individuals, providing the first step for (parapatric) speciation.

## Discovery of New Species

It is generally estimated that 15,000–18,000 new species are discovered every year, of which half are insects. This list includes also correction in the taxonomy or species that are moved from a family to another. Since 2008, the SUNY College of Environmental Science and Forestry releases on May 23rd (which corresponds to Carl Linnaeus's birthday) the list of the top 10 new species discovered the previous year (<http://www.esf.edu/top10/>).

There are different ways in which a new species can be discovered:

- *Expedition in remote areas.* There are many areas on earth that have not been explored yet, and can be home to species that have never been described. In December 2005, for instance, an international team of 11 scientists from Australia, the United States, and Indonesia travelled to the, until then, unexplored areas of Foja Mountains and discovered numerous new species (<http://news.bbc.co.uk/2/hi/science/nature/4688000.stm>). These included: 40 new species of mammals, many new plant species, including five new species of palms, four new species of butterflies, twenty new

**Species, Fig. 1** (a) Galápagos Islands, such as Isla Floreana, are volcanic islands visited by Charles Darwin in 1835; (b) bushes of the prickly pear cactuses (*Opuntia helleri*) on Isla Genovesa (Tower Island); (c) flowers of the yellow geiger (*Cordia lutea*); (d) male of the large ground finch (*Geospiza magnirostris*) singing during the rainy season; (e) female of the large ground finch

(*G. magnirostris*) on Isla Genovesa; (f) female of the medium ground finch (*G. fortis*) on Isla Santa Cruz; (g) male large cactus finch (*G. conirostris*); (h) male sharp-beaked finch (*G. difficilis*) feeding on cactus flowers on Isla Genovesa; (i) male warbler finch (*Certhidea fusca*) singing next to its nest (Abzhanov 2010; © 2010 The Royal Society)

species of frogs, and numerous new bird species. In some cases, researchers identify new species on the basis of the vocalizations they produce. Recently, Svensson et al. (2017) described a new species of dwarf bushbaby inhabiting Angola's Kumbira Forest which produces a different type of call from the other 18 known bushbaby species.

– *Examination of museum specimens.* New species can also be discovered in museum collections, where they were collected 50 or 100 years ago but their taxonomic classification was overlooked or specimens were often mislabeled. Recently, for example, Helgen et al. (2013) have described a new species of carnivorous mammal, the olinguito

(*Bassaricyon neblina*), that lives in the forests of Andes, Ecuador, and Colombia. Helgen and colleagues analyzed the fur and bones of the specimens that were stored in several museum collections and, through DNA testing, found out that this was a new species. Several zoos in the USA probably exhibited an olinguito between 1967 and 1976, but keepers mistook it for its close relative, olinga, and could not understand why the olinguito could not breed. The olinguito eventually died without being properly identified.

- *Genetic analyses.* The advancement of DNA techniques has offered researchers the opportunity to identify new species even when they are morphologically similar to another species and live in the same area. These species are also called cryptic species. DNA barcoding has become the most common technique to detect new species (Hebert et al. 2003). Through this technique, DNA is extracted from specimens that can be collected from the field, from museums, zoos, or other sources. A region of this DNA is then isolated. This region is commonly a 648 base-pair region in the mitochondrial cytochrome c oxidase 1 gene (“CO1”), located in the mitochondrial DNA, which has a mutation rate that is slow enough to be identical within the same species but fast enough to be different between species. The use of this DNA region to identify new species has been shown to be effective for many animal groups, such as birds, fish, butterflies, but not for plants, for which two DNA regions in the chloroplast are used instead. Once this region is isolated, its copies are replicated and sequenced. The sequence is then compared to the sequences of known species contained in the Barcode of Life Data Systems (BOLD) to understand whether the species is already known or is a new species (Fig. 2). Recently, barcode analysis has been used to identify a new gibbon species *Hoolock tianxing* (common name: skywalker hoolock gibbon), which is distributed on the east of Irrawaddy-Nmai Hka Rivers in China and had been previously considered to be the

same species as *H. leuconedys* (Fan et al. 2017). Although researchers had suspected that the two species were different, due to differences in morphology and vocalization patterns, only genetic analyses confirmed that the two were actually distinct species.

## Conclusion: The Importance of Taxonomy for Conservation

Taxonomy provides an important tool for the conservation of the species. The International Union for the Conservation of Nature (IUCN) is an organization that monitors the conservation status of the organisms, and in its Red List of Threatened Species, it classifies the species extinction risk into (1) Least Concern, (2) Near-Threatened, (3) Threatened (divided into Vulnerable, Endangered, and Critically Endangered), and (4) Extinct. By March 2014, among the 71,576 terrestrial and freshwater species assessed, 860 were classified as extinct or extinct in the wild, 21,286 were categorized as threatened, and 4286 were deemed critically endangered. Of the 6041 marine species for which we have enough data to assess their extinction risk, 16% were classified as threatened and 9% as near-threatened. Although the extinction of a species is a natural phenomenon that occurs at a rate of one to five species per year, the most recent estimates suggest that the current rate of extinction is 1000–10000 times higher and is largely human-driven (Pimm et al. 2014). Out of an estimated 8.7 ( $\pm 1.3$ ) million of eukaryotic species, only about 1.2 million species have been catalogued, leaving a total of 86% species on Earth and 91% of species in the ocean still undiscovered (Mora et al. 2011). With the high extinction rate that species face, many species disappear before they are discovered. In this context, identifying new species is key for their protection before they become extinct. Assigning the rank of “species” to a population is, thus, important both because it gives them legal protection and because it increases the awareness that the population is indeed unique (Zachos 2016).

## Species Cooperation

### ► Symbiotic Relationship

---

## Species-Specific Behavior

Sarah M. Huskisson

Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA

## Definition

Species-specific behavior refers to the repertoire of behaviors, innate or otherwise, that is shared by virtually all members of a given species.

## The Origins of Species-Specific Behaviors

The characteristic behaviors a species exhibits can serve social, reproductive, nutritional, or other functions within the context of an animal's natural history. Species-specific behavior refers to the standard set of behaviors exhibited by most, if not all, members of a particular species. For example, while most species of deer leap away from a perceived source of danger once startled, due to genetic differences, white-tailed deer (*Odocoileus virginianus*) gallop but mule deer (*O. hemionus*) stot. These different forms of movement would be considered species specific.

Species-specific behaviors can arise from minor modifications to preexisting behaviors. These changes can occur anywhere from an individual's genetic environment to its social environment. Both instinct and individual experience play a significant role in shaping species-specific behaviors, as can social learning from parents or other individuals in an animal's life. White crowned sparrows (*Zonotrichia leucophrys*), for example, learn how to produce sophisticated songs within the first weeks of life. Interestingly, birds' ability to learn song characteristics is also coupled with an innate preference for songs typical of its own species. Imprinting is another form of learning that is characteristic to a few species, notably ducks and geese. This type of learning occurs in early development, typically right after hatching, in which offspring associate the first animal they see with a maternal figure. This visual stimulus triggers a suite of behaviors, like following, that encourages further social learning and survival for hatchlings. In cases where hatchlings do not immediately see their biological mother, they may imprint on another species.

In contrast, other species-specific behaviors may be instinctive, like head-bobbing shown by green anole lizards (*Anolis carolinensis*), a display behavior used in territorial or courtship contexts that can be performed from birth. Instinctive behaviors may be accompanied by fixed action patterns (FAPs), which are produced by innate releasing mechanisms, types of neural networks,

in response to a stimulus or releaser from the organism's environment. The greylag goose (*Anser anser*) provides a classic example of a FAP: if an egg rolls out of the nest while a goose is incubating, they will automatically begin tilting their head from side to side in an attempt to retrieve the egg. Geese have been observed to continue these specific motions even in the absence of an egg (Lorenz and Tinbergen 1938), hence the "fixed" nature of a fixed action pattern. Once triggered, a FAP will run to completion, regardless of changes in circumstance.

Some species-specific behaviors can be linked back to physical structures within the animal brain. In many experimental studies, animals lose the ability to perform instinctive or necessary behaviors after losing function in certain brain structures. Hamsters (family Cricetinae), for example, have been shown to lose play and maternal behaviors after receiving brain lesions at birth (Murphy et al. 1981). This reveals that an intact limbic system is necessary to call innate behaviors to action with the appropriate stimulus. Additionally, chemical receptors in the brain or elsewhere in the body encourage characteristic species behaviors, such as monogamy in prairie voles (*Microtus ochrogaster*) that is mediated by oxytocin. Ultimately, healthy structures and normal functioning are imperative for the execution of both innate and learned species-specific behaviors.

Regardless of origin, species-specific behaviors fulfill distinct and necessary roles in an animal's life. The disruption or eradication of such behaviors can be detrimental to the animal. When animals become heavily influenced or managed by humans, it is of paramount importance to maintain species-specific behaviors to ensure a healthy and high-quality life, which in turn can support species preservation.

## Importance Among Wildlife

### Conservation

In wild populations, species-specific behaviors can be influenced by external pressures caused by anthropogenic activity, which could include

alterations in ambient noise, lighting, and activity patterns, among other factors. Noise pollution from anthropogenic disturbance has caused many species of birds, primates, and cetaceans to alter their characteristic vocalizations. Extra noise can impede signal transmission, not only affecting qualities like timbre and the frequency at which signals are received, but also altering the signaler's innate behavior (e.g., calling at a different pitch than would be typical). If group members fail to hear or recognize the call directed toward them, there is potential for increased predation or disbanded social networks (Barber et al. 2009).

Alterations to natural light cycles due to persistent artificial lighting can disrupt many signals animals use to engage in species-specific behaviors, such as when to commence foraging, seek shelter, and mate. Bats have been observed to change flight patterns and delay commutes in response to a greater presence of light at night, affecting their circadian rhythm and innate predisposition to a nocturnal lifestyle. Alternatively, one change that is becoming more prevalent across taxa is diurnal species' move to nocturnal activity to avoid encounters with humans. A recent meta-analysis of 76 species across the world revealed convergent patterns of human avoidance, namely, ignoring innate tendencies to be active during the day. In the immediate, becoming nocturnal to avoid humans seems an effective way to coexist on an ever-crowding planet (Gaynor et al. 2018).

With human presence encroaching upon wildlife and wild places, changes in species-specific behavior may mean immediate safety for individual animals, but these alterations in behavior may have long-term negative ramifications, the potential for extinction among them. One case is that of the sable antelope (*Hippotragus niger*). While listed as Least Concern by the International Union for the Conservation of Nature (IUCN) as of 2018, sable antelope have been, in recent years, waiting until dark to visit waterholes in order to avoid humans, despite the overwhelming presence of predatory animals. Sadly, this means that more antelope are becoming prey, and time will tell how this impacts the species as a whole.

## In Captivity

Regardless of environment, species-specific behaviors are often considered to be the "gold-standard" metric of animal behavior and are imperative in considering the effective management and welfare of wildlife housed in captive settings, such as zoos, sanctuaries, and laboratories. Taking cues from animals' wild counterparts to provide targeted and holistic behavioral management can positively influence reproductive behavior and reintroduction success, among other factors. For example, many species of primates prefer to sleep in elevated areas at night so they are not an easy target for predators and smaller primates like tamarins prefer sleeping areas that provide added concealment over more open areas (Caine 2017). In captive settings, care staff may provide their primates with raised sleeping platforms and bedding materials that offer security and concealment for animals.

Animal managers often monitor and seek ways to encourage species-specific behaviors, as they are considered to be desirable. When considering ways to increase the performance of species-specific behaviors that can be measured quantitatively, manipulating animal environments is a common practice. From myriad studies across taxa, it has been noted that increasing the complexity of an animal's habitat or exhibit space increases species-specific behaviors and consequently reduces atypical or undesired behaviors (Alligood, et al. 2017; Veasey et al. 1996). It is also critical to understand how an animal perceives and uses enrichment and whether it elicits the species-specific behaviors that it is intended to stimulate. In cases like this, preference testing can provide a glimpse into the animal's point of view and helps care staff determine if well-intentioned changes are meaningful (Alligood et al. 2017). Additionally, behavioral evaluations can allow managers to see exactly how an animal is using enrichment, and they can then follow up with necessary adjustments to maximize activity and benefit to the animal (Alligood et al. 2017). While the nature of managed environments may differ greatly from an animal's natural habitat, creating a dynamic space with which the individual readily

interacts can promote a “close-to-natural” repertoire of behaviors (Clubb and Mason 2007), with an emphasis on promoting each species’ species-specific behaviors.

While deviations from typical behaviors may reflect compromised welfare, determining whether or not a behavior is harmful, in some incidences, warrants further investigation. In the case of great ape coprophagy, observed instances of this behavior are often used as an indication of compromised well-being. Interestingly, wild apes, particularly chimpanzees, have been seen to consume feces in the wild, though at lower rates than seen in captive populations. While ape coprophagy may indeed be more prevalent in captivity, it may not necessarily be indicative of lessened quality of life. Another example includes zoo-housed giraffes: In the wild, giraffes might be more active due to foraging and predator avoidance. However, captive giraffes can be more sedentary, as resources are plentiful and threats are minimal. Clearly, captivity can alter behavior, and thus behaviors should be evaluated in their evolutionary and situational contexts (Birkett and Newton-Fisher 2011; Clubb and Mason 2007; Hopper et al. 2016; Veasey et al. 1996). Given the rarity of some exotic species housed in captivity, it may be difficult to know or acquire the knowledge needed to manage by and encourage the expression of species-specific behaviors. Subsequently, this may make objective welfare studies and evaluation a challenge, and care staff may be forced to draw generalizations from related species and subspecies (Veasey et al. 1996).

## Sperm Competition

Kate L. Durrant

School of Life Sciences, The University of Nottingham, Nottingham, UK

### Definition

Sperm competition is defined as a form of sexual selection that occurs when ejaculates from multiple males compete for the fertilization of an individual female's ova. Most female organisms are known to mate with multiple males, so sperm competition is considered to be a widespread and powerful evolutionary force. Competition between males may occur before or after copulation, to either prevent or win competitions, leading to the evolution of numerous traits to enhance fertilization success. Sperm competition *sensu stricto* refers only to the competition between ejaculates after two males have inseminated the same female.

### Introduction

The theoretical basis of sperm competition was formalized by Parker (1970) and relied on several key observations. The first is that the evolution of internal, or close to internal, fertilization was not only subject to natural selection pressures to maximize fertilization chances for each ovum, but also sexual selection between competing males to place their spermatozoa as close to the female's ova as possible in order to achieve fertilization. The evolutionary advantage to a male that competes successfully means that sexual selection continues after copulation if females mate with more than one male. Establishment of sperm competition as a widespread and powerful evolutionary force became possible with the body of evidence that built up during the 1970s–1990s that demonstrated the widespread existence of female polyandry: multiple mating by females with different males (Taylor et al. 2014). Bateman's principle (Bateman 1948) states that

males can increase their reproductive output by securing extra mates, but females cannot, being limited by the costs of egg production and bearing young, which implies that females should not seek multiple mates in the way that males do. However, although polyandrous mating can be costly for females, in terms of increased predation or disease risk, or expenditure of time and energy, or damage by mating males, it has been demonstrated in many taxa that females mate with multiple males, securing benefits for the female (from gaining resources) and her offspring (from gaining advantageous traits) (Taylor et al. 2014). Polyandrous mating is the driver for sperm competition and it is the “risk” that is countered by the evolution of competitive traits in males.

The final observation that completed Parker's (1970) theory of sperm competition is that the production of sperm is constrained by energy costs. Spermatozoa, despite their generally small size, are not “cheap” to produce and can take energy away from other forms of mating effort. Once one assumes that there is a constraint on sperm production and supplies are not limitless, you can build theoretical models that predict how different males and/or species will respond to differing levels of “risk” from sperm competition. For example, the raffle model (Parker 1982) predicts that a male's likelihood of successful fertilization increases with the greater number of spermatozoa he contributes to the competing ejaculate pools; that is, he has more “tickets” in the form of individual sperm in the raffle and therefore more chances of winning the “prize” of fertilization. The raffle model allows greater understanding of the evolution of morphology of spermatozoa cells, especially in comparison to female gametes. The size disparity between the typically small male and larger female gametes is known as anisogamy and can be extreme in many species. Sperm competition promotes the maintenance of anisogamy and partly explains the observation, particularly in vertebrates that spermatozoa tend to be numerous and tiny (Parker 1982). It also explains why spermatozoa between and within species tend to be highly morphologically variable, as different taxa develop various adaptations for competitive

fertilizing capacity, working within their particular constraints of physiology and environment. Sperm are considered to be the most morphologically diverse cell of all, and in some taxa, it is possible to identify individual species purely by the morphology of their spermatozoa (Birkhead et al. 2009).

The evolution of sperm competition was initially modeled using an Evolutionarily Stable Strategy (ESS) approach because the fitness of a given sperm allocation strategy depends on the strategies played by other males in the population (Birkhead and Møller 1998). The strategic question here is “How much of a male’s total reproductive effort should he spend on sperm?” Males are competing against other males, using a specified range of ejaculate strategies, and it is their ejaculates which compete. In this instance, females are assumed to not display any preference for any male’s strategy. These sperm competition “games” are used to predict how individual males should respond when the risk and intensity of sperm competition within a species varies. Risk models refer to the probability that an individual female will mate with more than one male. Intensity models were introduced mainly to incorporate group-spawning species like some fish, where males compete in groups and ejaculate as a female simultaneously releases eggs, leading to intense levels of sperm competition. Where there is a fixed total budget for reproduction, expenditure on the ejaculate (more sperm and/or enhanced sperm) increases the gain per mating, but necessarily reduces the expenditure on mating (finding and accessing mates), which reduces the number of matings achieved in total. Fitness is the mathematical product of gain per mating and the number of matings achieved.

Intraspecific variation in sperm competition risk and intensity makes different predictions for species depending on various interactions between aspects of life history and phenotype. At its most basic, the greater the risk or intensity of sperm competition, the more all males within a species should spend on ejaculates to successfully compete, and this is a common phenomenon observed across species. However, there are different pathways to fertilization success that are

possible within a species, and so they require consideration. Here, the raffle model expands to take into account phenotypic differences between males in a species, and leads to two new models: the “fair” raffle and the “loaded” raffle (Birkhead and Møller 1998).

In a fair raffle, the males have no information about the current risk of sperm competition, and the ESS under a risk model is that males should expend a proportion of their mating effort solely on their ejaculate at the rate of one half of the proportion of females that mate polyandrously. The ESS for the intensity model requires males should spend almost their entire mating energy budget on ejaculates and very little on gaining matings. In a loaded raffle, a wider range of circumstances are incorporated into the model, which reflect prior information males may have, or phenotypic constraints they may be operating under. For example, males may be the second of two males to mate with a female, and knowing this, may increase or decrease the allocation of individual sperm to their ejaculate, depending on whether last or first-male sperm precedence operates to secure fertilizations in that species. Alternatively, males might be acting as either territorial males or sneaker males, whereby large size and greater resource holding potential are traits of the former, and small size and drab coloration may be traits of the latter. Males who fit the sneaker phenotype are taking part in a loaded raffle and should expend nearly all their mating energy budget on ejaculates.

Under a risk model, with increasing levels of sperm competition in a loaded raffle, each male should make an equal ejaculate contribution to every female regardless of whether he is the first or second male to mate with her, because the chances are high that the female will mate again if he is first and he must compete against the other male if he is second. Under the intensity model, in a loaded raffle, the prediction is the more males that are present at fertilization, and therefore the higher the intensity of sperm competition, the less each male should allocate to his ejaculate expenditure. He should save his energy to expend on ejaculates only when the prevailing intensity of sperm competition is low.

When females control the rate of mating, as is likely under natural conditions, and males face a trade-off between allocating a set amount of energy between pre-copulatory competition and post-copulatory competition, sperm competition models move towards the general model proposed by Parker et al. (2013). In this model, the trade-off between pre-copulatory male-male competition and post-copulatory sperm competition is taken into account as before. The trade-off takes the form of any developmental trait that enhances a male's competitive ability against other males, causing the phenotype in question to have its sperm production reduced. There are also parameters for the number of males competing for each mating and the competitive weights of males, determined by their investment in pre-copulatory traits that will allow them to win male-male competitions, which is new to this model compared with its predecessors. This allows examination of any level of male-male mating contest, from a simple dyadic interaction to a scramble contest for mates and allows the parameters to be considered independently to assess their effects.

Predictions stemming from Parker et al.'s (2013) general model indicate that males should invest in weaponry in greater amounts as the density of competing males decreases. Males should also respond to higher densities of males by investing in greater ejaculate production. Therefore, in breeding populations of high male density where males are at the highest risk of sperm competition, males should produce larger testes than expected for their body size. In breeding populations with a relatively low density of males, a male should invest in large body size or weaponry to control access to females and prevent other males mating with a female he has mated with. This model can be considered simplistic in that it does not separate out the various components of male pre-copulatory mating effort, such as searching for mates, participating in aggressive contests or include general increased mortality costs, but it still provides a robust framework for exploring the effects of male-male competition both prior to and after copulation. The theoretical basis of sperm competition indicates its potential to act as a powerful evolutionary selection

pressure promoting and maintaining both physical and behavioral traits in order to secure fertilizations.

## General Mechanisms of Sperm Competition

Given female polyandrous mating, males face a problem depending on whether there is random or nonrandom fertilization of ova by a set of sperm, known as the fertilizing set, which is contributed to by multiple males (Simmons 2001). Where fertilization is random, there is only a slight advantage for males to be able to determine the virginity or otherwise of a female, but the likelihood that she will mate again after he mates with her is valuable to know. If each male contributes equally to the fertilizing set and there is random mixing of the sperm immediately prior to fertilization, then this equates to a fair raffle, where every sperm in the set has an equal chance of fertilization. Given a certain rate of sperm transfer, through altering copulation duration or the number of ejaculations, males can manipulate the number of their sperm present in the fertilizing set.

If the sperm represented in the fertilizing set is no-random, then sperm displacement has occurred. A male's chance of success depends on whether they are the first or the last male to copulate with a female prior to fertilization of her ova (Simmons 2001). Taxa differ in the utilization of sperm, and it may either be an advantage to be the first or the last male to mate with the female in terms of securing fertilizations, depending on the physiological patterns of storage and use of sperm by the female. Although sperm mixing is the most common fertilization pattern for a female that has mated polyandrously, first-male sperm precedence is often found in crustaceans and last-male sperm precedence usually found in the insects (Shuster and Wade 2003). Many of the most informative studies for understanding these patterns of sperm storage and use were conducted in insects (Simmons 2001), but the females of birds, internally fertilizing frogs, reptiles, and sharks also store sperm for significant periods of time and males of these species have evolved mating

strategies for engaging in sperm competition (Birkhead et al. 2009).

Sperm storage by females has been observed in many species and females stand to gain both direct and indirect benefits from storing sperm (Birkhead et al. 2009). The most basic reason for storing sperm is that females may remain receptive and/or lay eggs over a prolonged period and could risk running out of sperm if they do not carry a supply of it. Although one of the presumed outcomes of intense sperm competition is to produce an ejaculate of numerous and tiny sperm that can fertilize all the ova a female has (Parker 1982), an alternative evolutionary outcome is for males to travel between many females, mating frequently but contributing few sperm per female and tolerating partial paternity of any given batch of offspring. In this case, males strategically allocate only some of their ejaculate per female, and this may require females to mate multiply to ensure complete fertilization of her ova (Shuster and Wade 2003).

Although sexual females require fertilization in order to reproduce, and across taxa many components of seminal fluids aid in ovulation and preparation for reproduction in the female, not all ejaculate components are beneficial to females (Shuster and Wade 2003). For example, the female mammalian reproductive tract presents a hostile environment to sperm because of raised acidity and physical impedances to travel; this is not solely to protect against pathogens but also to actively target sperm (Arnqvist and Rowe 2013). Sperm viability is challenged by conditions in the female reproductive tract to eliminate weaker sperm and avoid ova being fertilized by multiple sperm, a condition known as polyspermy, which leads to nonviable zygotes. Some sperm do not survive in the reproductive tract, or later in storage, and so seminal substances have evolved to aid sperm longevity after ejaculation.

When determining patterns of sperm storage and use as it applies to sperm competition, it must be noted that ejaculate-female interactions are currently poorly understood, and many of what appear to be adaptations or counter-adaptations between coevolving males and females may be by-products of other physiological processes

(Arnqvist and Rowe 2013). Similarly, the role of cryptic female choice, whereby females control fertilization post-copulation by mechanisms that allow selection of one male's sperm over another, is also poorly understood (Birkhead and Møller 1998). These are areas ripe for further investigation as imaging, *in vitro* and *in vivo* techniques and molecular methods improve.

The theoretical possibility of intra-ejaculate sperm competition has been debated extensively (Birkhead and Møller 1998). It is possible that sperm within a fertilizing set may compete against each other if relatedness between sperm is low, as it would be in diploid species. In haplodiploid species, relatedness between the haploid sperm would be one and competition within an ejaculate should be absent. There is little evidence for intra-ejaculate sperm competition although there are observations that support its theoretical existence, such as the example of one of the few species with five distinct sperm morphs, an unusually high number, being haplodiploid, the hymenopteran wasp *Dahlbominus fuscipennis* (Birkhead and Møller 1998). Some sperm morphs are incapable of fertilizing and will assist other sperm within the ejaculate to fertilize successfully. Such traits would not be expected under intra-ejaculate sperm competition. Empirical evidence for intra-ejaculate sperm competition is rare, but Hemmings et al. (2016) found morphological differences between sperm trapped in the perivitelline layer of fertilized eggs and sperm obtained from feces of Zebra finches (*Taeniopygia guttata*). The sperm that reached the ovum had shorter heads and shorter heads relative to overall length in comparison to sperm randomly sampled from fecal deposits, which was interpreted as indicating "successful" sperm possessed traits for greater efficiency in swimming. While this does not demonstrate intra-ejaculate sperm competition, it does show that morphological and functional differences may exist between the sperm that are able to fertilize ova and other sperm.

There is also limited evidence for sperm cooperating within an ejaculate, also known as sperm altruism (Birkhead et al. 2009). In some species of rodents, the spermatozoa have an apical hook on the head that allows sperm to form large

sperm trains. The hooks are flattened against the head in the epididymis, and are unfurled about a minute after ejaculation. The hooks grip other sperm hooks, or onto the tails and sperm trains form within the female reproductive tract. These trains swim at a higher velocity than individual sperm and have an advantage in reaching the ova first. It is suggested that the sperm may possess a “green beard” recognition allele, or other genetic mechanism, to enable cooperation between the spermatozoa from a single male. Rodent species under the highest risk of sperm competition produce sperm with the most pronounced apical hooks. In other taxa, New World marsupials especially, sperm form pairs in the epididymis that result in a faster swimming speed compared to single sperm, due to the paired tails beating in unison (Birkhead et al. 2009). These morphological and behavioral traits are presumed to allow the sperm from a single male to successfully compete against the ejaculates from rival males.

### Offensive Adaptations for Sperm Competition

A spermatozoon cell is made up of four main parts: acrosome (or head), nucleus, mitochondria, and flagellum (or tail); however, sperm have been found in species lacking any one of these parts, for example, the anucleate parasperm found in gastropods and Lepidoptera. Adaptations to sperm morphology are one of the most commonly observed evolutionary responses to intense sperm competition (Birkhead et al. 2009). Biologists have studied sperm morphology for hundreds of years, since the invention of the microscope, and noted the species-specific nature of sperm cell morphologies, and, in some species, high levels of sperm morphological aberrations, or an ability to produce multiple sperm types (sperm heteromorphism), or very large sperm (sperm gigantism).

High levels of morphologically aberrant sperm, for example having two tails or no head, within the ejaculate is a response to relaxed sperm competition. Eurasian bullfinches (*Pyrrhula*

*pyrrhula*) produce highly variable sperm morphologies within their ejaculate and this evidence, combined with overall sperm morphology and relative testes mass, indicates a species where males face little risk of sperm competition (Birkhead and Immler 2007). By contrast, dunnocks (*Prunella modularis*) are known to engage in multiple copulations in a highly flexible mating system and produce a greater consistency of sperm morphologies within an ejaculate (Birkhead and Immler 2007). These patterns of consistent “high quality” and aberrant “low quality” sperm production are found across many taxonomic groups, including insects, mammals, and birds. This indicates that quality control of sperm production is a costly process that is not undertaken when the risk of sperm competition is low, which is consistent with Parker’s (1970) predictions about the costly nature of producing ejaculates.

Sperm heteromorphism is found in many taxa, from gastropods to tardigrades, annelids to spiders, and insects to chordates such as fish (Birkhead et al. 2009). Many taxa have two distinct sperm morphologies, but a few such as the Apple snails (Ampullariidae) have three or more. The morphology capable of fertilizing is called eusperm or eupyrene sperm and the morphs lacking some or all of the male’s DNA, and therefore incapable of fertilization, are called parasperm, and all morphs are produced in the testes. Their function varies between taxa. The giant parasperm found in mollusk species appear to act as transport for the smaller eusperm, but in Lepidoptera, parasperm are responsible for delaying female remating and are also a necessary component of the fertilization capacity of eusperm in some species. In other taxa such as gastropods and mammals, parasperm are responsible for disabling sperm from other males that are encountered in the female reproductive tract, and for blocking access to the female’s sperm-storage organs for any subsequent male’s ejaculates. All of these functions are consistent with an adaptive male response to the risk of sperm competition.

Sperm gigantism is the production of extremely large individual sperm cells. Perhaps

the most distinctive example is the giant sperm cells produced by the fruit fly *Drosophila bifurca*, which at 5.8 cm long is one of the largest spermatozoa in the animal kingdom. Each male can only produce and store six individual sperm at a time. The tendency for giant sperm in many *Drosophila* species is related to the effects of physical competition between sperm cells where displacement of rival male sperm takes place in the female reproductive tract. The giant sperm physically prevent any other sperm accessing the ova, and the overall small body size of the fly allows this mechanism to succeed. Immler et al. (2011) contrasted this pattern against the tendency for larger organisms such as passerine birds to produce tiny and numerous spermatozoa when operating under a raffle model of sperm competition. There is a trade-off observed between sperm size and sperm number that allows the evolution of giant sperm when organisms become smaller-bodied and the risk of excessive dilution in the female reproductive tract is lessened.

Spermatozoa are collectively transferred either to the environment in externally fertilizing species, or to the female within an ejaculate. Ejaculates also contain seminal fluid that assists in the transport of sperm and consists of biochemical products from accessory glands that perform various functions to enhance fertilization success. Sperm may spend considerable time within the female reproductive tract before fertilization, and the ejaculate interacts with, and counters some of the defenses of, the female reproductive tract during this time to maintain viable sperm cells (Birkhead et al. 2009). In the insects, accessory glands vary in number and developmental origin, and they produce a wide range of products (Leonard and Cordoba-Aguilar 2010). This diversity across taxonomic groups indicates rapid and divergent evolution of a suite of traits under strong selection. Accessory gland products may stimulate oviposition or suppress re-mating in females; they may remove rival sperm or facilitate sperm transport, storage or activation. The dose-dependent effects of many accessory gland products indicate that the males that can produce the greatest amounts, generally from larger glands, will have a fertilization advantage. In species of

fireflies (Coleoptera) and moths (Lepidoptera), accessory gland size is positively associated with greater risk of female polyandrous mating, suggesting the glands and their products play a positive role in fertilization enhancement and sperm competition (Leonard and Cordoba-Aguilar 2010).

Spermatophores are conglomerates of sperm in seminal fluid and other components that can either be deposited in the environment for later collection, or transferred directly to a female. They are found in invertebrate taxa such as cephalopods and Lepidoptera but have been extensively studied in the bushcrickets, Orthoptera: Tettigoniidae, due to the extreme sizes of spermatophore that some species produce (Wedell 1993). In a comparative study, Wedell (1993) found that one species of bushcricket produced a spermatophore that was 28% of the male's body weight, while some species produced smaller spermatophores that were just 2% of male body weight. There was a significant positive correlation between the size of the spermatophore and the length of time before a female mated again, which also correlated with male fertilization success. Although spermatophores are often eaten or otherwise absorbed by females to provide nutrients for egg production, they do not appear to be only or even mainly nuptial gifts. In many cases, spermatophores have evolved to provide protection and assistance to sperm to enhance male fertilization success (Wedell 1993).

Sperm production relies on the physiological capabilities of the testes and in general the greater the amount of testis tissue, the more sperm that can be produced. Biologists assume that testes size is correlated to the energy devoted to sperm production and to sperm production rates, and this assumption has largely been upheld (Parker et al. 1997). As a result, a standard proxy for the level of sperm competition across or within species is the size of the combined testes relative to overall body size. The larger or heavier the testes are in relation to body size, the greater the potential to produce large quantities of sperm, and the higher risk of sperm competition the males of the species are thought to face. The relative testes mass is often expressed as the gonosomatic index or GSI

( $= 100 \times \text{gonad weight/somatic weight}$ ) and has been measured across numerous taxa, including: primates, birds, mammals, butterflies, and fishes; all of which demonstrated the predicted positive correlation between risk of sperm competition, as indicated by male density or instances of female polyandry, and relative testes mass.

Among internal fertilizers, penile morphology has been shaped by the pressures of sperm competition into many forms to enhance sperm delivery and/or remove the sperm of rivals. Here the term “penis” is shorthand for any intermittent organ that delivers sperm during copulation. Penile morphology may be elaborated to such a degree that it is no longer reasonable to assume a function for insemination alone. Penile morphology adapted for sperm competition has been observed in the gastropods, arthropods, and vertebrates such as birds (waterfowl) and mammals (Birkhead and Møller 1998). A wide variety of morphological adaptations have been observed in the arthropods, some are elongated with flagella or other structures that can fit in the spermathecal duct to place sperm close to the site of fertilization within the female. One of the most extreme examples is found in the rove beetle *Aleochara tristis* (Gack and Peschke 2005). Males possess a long penile flagellum which is twice the male’s body length, while females have a correspondingly long spermathecal duct. The flagellum is stored coiled within the male’s main penile structure when not in use. After copulation, males engage in a particular behavior to retract the flagellum without it snapping or tangling, both of which would prevent the male mating again. The male must “shoulder” the flagellum while retracting it from the female, trapping it between his wing case and body while maintaining tension and moving away from the female. This allows the male to gradually feed the flagellum back into his body “in an orderly fashion,” ready to mate again. The de-coupling process takes about 90 seconds (Gack and Peschke 2005). This example shows the additional behavioral adaptations that accompany extreme morphological adaptations to sperm competition, as well as the mechanisms that species employ to overcome

constraints imposed by these extreme morphologies.

Waage (1979) was the first to observe that some penile morphologies were able to remove the sperm from rival males. He noted that damselfly, *Calypteryx maculata*, Odonata, penis heads have backwards-facing spines and horn-like structures on the head, and males perform an undulating motion during copulation that was demonstrated to remove sperm already present in the female’s sperm storage organ. Since then, the penis “scrapers” of many species have been described, and additional functions also detected. In the seed beetle, *Callosobruchus maculatus* (Crudginton and Siva-Jothy 2000), the penis is covered in spines that damage the female reproductive tract during copulation and this reduces female polyandry and longevity. The reduction in female longevity has been thought to be off-set in some species, like the seed beetles, by enhancement of female fecundity through products in seminal fluids, although this has yet to be established.

At least 36 taxa spread over 13 Classes of animals, from polychaete worms to amphibians, have been confirmed to engage in some form of copulatory wounding (Reinhardt et al. 2015). A smaller number of taxa have attempted to bypass the usual route to internal fertilization through the female reproductive tract and attempt to place sperm as close to the ova as possible by piercing directly through the female’s body wall. This insemination behavior also bypasses the female’s sperm storage organs, where sperm may become nonviable over time or be displaced by later-inseminating males. The best-studied group are the Cimicidae bedbugs, where all of the approximately 100 species fertilize the female by piercing the body wall with the penis (Reinhardt et al. 2015). In order to successfully fertilize using this “traumatic insemination” mating behavior, these taxa all have a penis with a sharpened tip, in some cases very similar to a hypodermic needle.

Among mammalian species, a variety of penile morphological elaborations are thought to play a role in sperm competition. Mammalian penises have spines, corrugations, fingers, or the entire

structure may be corkscrew-shaped (Birkhead and Møller 1998). The baculum, or os penis, is a bone that contributes to stiffening of the penis and allows prolonged copulation in mammalian groups such as bats, primates, rodents, and many carnivores. Keratinized penile spines are also found in a number of mammals such as primates, bats, and rodents. The presence of penile spines and/or the baculum is positively associated with relative testis mass in 296 species across four Orders of mammals (Birkhead and Møller 1998). Penile spines have also been implicated in inducing ovulation in groups such as the Carnivora, especially in felids, but there is no confirmed relationship between the presence of spines and induced ovulation. In the galago, or bush baby (Galagidae), the penile spines were thought to form a “genital lock” to allow prolonged mating. In general, mammalian penile adaptations appear to either facilitate prolonged copulation, or, in the case of spines, to prevent or delay re-mating.

Prolonged copulation duration is an adaptive trait that may increase the number of sperm transferred to the female, thereby enhancing a male's chances of fertilization. Copulation duration has been most closely studied in yellow dung flies, *Scatophaga stercoraria*, where the usual frequency-dependent game theoretic approach for understanding sperm competition is switched to a mathematic model following the Marginal Value Theorem (MVT) normally used to understand optimal foraging behavior (Birkhead and Møller 1998). The MVT is used as the base model for copulation duration as all the expenditures are expressed as time costs rather than in energy expenditure, which is a more accurate reflection of the costs to the copulating male. Copulation duration in dung flies depends upon the size of the male, and modeling and field studies have found that smaller males should spend more time in copula than larger males. This is because larger males can physically displace sperm at a faster rate, and they are also more successful at interrupting a mating pair during oviposition and displacing the first male's sperm with his own, reducing the time spent. Therefore long copulation times should be observed in species where the male benefits from increased time

to transfer sperm and has little chance of taking over an already-copulating pair.

These adaptations are all part of a suite of traits that males may employ during or after copulation to enhance fertilization success. Species may possess several of these traits, depending on the risk of sperm competition males may face, and traits may be used strategically in response to sperm competition risk. Males may determine the risk of sperm competition by assessing the mating status of females or estimating the density of competing males to available females. The strategic allocation of sperm to an ejaculate is one such example where individual males may alter their mating effort in response to sperm competition risk and save energy by allocating fewer sperm when that risk is very low. The next section deals with traits that attempt to avoid sperm competition before it happens, by restricting opportunities for female polyandry and often these traits consist of behaviors that occur before copulation.

## Defensive Adaptations for Sperm Competition

Many of the traits that prevent sperm competition occurring are also adaptations that control female accessibility. Females will attempt to avoid or evade these mechanisms, leading to conflict between the mating interests of males and females, known as sexual conflict. Rival males will also attempt to overcome these obstacles as part of male-male competition. Therefore, there is no strict definition that designates a trait as being “for” sperm competition when it also circumvents female choice, prevents male-male competition, and is still subject to the influence of natural selection from both biotic and abiotic factors.

Mate guarding is a widespread behavior that comes in a variety of forms. Any extended association between a mating pair that is longer than the time required for successful copulation is indicative of mate guarding, but often descriptions of the behavior rely on simple observations,

without quantifying the costs and benefits or determining if the behavior leads to increased fertilizations for the male (Simmons 2001). The presence of and type of mate guarding behavior that a species displays depends on a large number of factors including: the risk and intensity of sperm competition, whether first- or last-male sperm precedence operates, the synchrony of female maturation, the population operational sex ratio, how long females remain receptive to mating, and whether males can assess female mating status (Elias et al. 2014).

Mate guarding involves preventing the female from accessing other mating partners and can occur either pre-copulation or post-copulation. Three basic forms are observed, noncontact, contact and copulatory (Simmons 2001). Non-contact mate guarding behavior can involve closely following or herding fertile females, as seen in many ungulate herding mammals such as deer and antelope. Males may stay physically close until the female is receptive, partly to guard against rivals, but also because receptive females are rare, as seen in clown shrimp *Hymenocera picta*. In other taxa, males may block females into a burrow or other structure and aggressively defend the burrow entrance so that other males cannot access her, as in dung beetles *Onthophagus acuminatus*. Contact mate guarding requires males and females to be physically touching. Some taxa using this strategy ensure first-male sperm precedence by fertilizing females as soon as they become mature, by physically holding on to a female before she reaches maturity and mating with her as soon as she does (Simmons 2001). Prolonged copulation duration can also be considered a form of copulatory mate guarding (Birkhead and Møller 1998). Some species show a flexible set of strategies, such as the jumping spider, *Phidippus clarus*, which either clasps an immature female and guards her until maturity, or searches for virgin females (Elias et al. 2014). In this spider, each of these strategies was shown to be equally successful in terms of reproductive success.

A male that guards his mate is losing opportunities to find and fertilize other receptive females. Some species have developed a way to “guard”

females remotely by attempting to prevent re-mating by blocking the female reproductive tract. Copulatory or mating plugs consist of various products that block the female genital opening. Many insect species produce copulatory plugs from accessory gland products, which are sufficiently malleable to completely block the female oviduct (Parker 1970). Many species of spiders and mites also produce plugs, as do nematodes and reptiles (Birkhead and Møller 1998). This type of plug is also observed in a number of mammals such as rodents, bats, insectivores, primates, and marsupials. Some rodent mating plugs are a gelatinous accretion of seminal products that later harden to block or glue together the reproductive tract. Females may expel them later, but depositing a mating plug gives the male a significant time advantage to allow his ejaculate to fertilize her ova before she mates again.

Some taxa utilize their genitalia as mating plugs to prevent re-mating. This is frequently a terminal event, in that it can prevent the male re-mating and often results in death. “Explosive ejaculation” is recorded in hymenoptera such as the honeybee (*Apis mellifera*), where the force of ejaculation rips off the male endophallus and leaves it attached to the female genital opening (Paxton 2005). This and associated mucus forms a visible signal that the queen has been mated, yet this does not always prevent re-mating. Other drones will remove the endophallus and mate with her during the nuptial flight and she mates on average more than 17 times. Spiders generally mate by priming their specially modified pedipalps with sperm and inserting them into the female genital opening. Some species, such as the St Andrew’s Cross spider (*Argiope keyserlingi*) snap these off to plug the female and prevent re-mating, restricting the male to two copulations (Herberstein et al. 2012). In the St Andrew’s Cross spider, the plug formed by the broken pedipalp was determined to be an effective barrier to female re-mating. These are often seen as extreme adaptations to counteract the risk of sperm competition, but if at least some paternity is assured by these morphological and behavioral traits then they will be maintained in the population.

## Trade-Offs Between Pre- and Post-Copulatory Sperm Competition Traits

Under Parker et al.'s (2013) sperm competition model, trade-offs are expected between traits that enhance the chances of monopolizing females pre-copulation and traits that enhance the chances of successfully fertilizing ova post-copulation. This is due to the central idea of the cost of traits to an individual operating under a fixed energy budget. Males are assumed not to be able to pay the costs of both elaborate traits for winning male-male competitions and traits that enhance fertilization success under a high risk of sperm competition. Many of the adaptations presented here potentially pose significant costs to the males bearing them, from genital modifications or giant sperm to the physiological capacity to guard a female or copulate with her for prolonged periods of time, although the costs often remain unquantified. More attention has been paid to the costs of traits used in pre-copulatory male-male competitions, in terms of the production of weaponry or large body size. It is less common that the costs and trade-off in traits used in both the pre- and post-copulatory phases of sexual selection is specifically addressed, but the body of evidence for such a cost trade-off has been growing.

There is evidence for Parker et al.'s (2013) predicted trade-off between pre- and post-copulatory trait investment from organisms as diverse as fish, frogs, birds, mammals, and insects. Arctic charr, *Salvelinus alpinus* (Rudolfson et al. 2006), represent a good example of a species operating under intense sperm competition. They are externally fertilising teleost fish that are able to rapidly adjust their investment strategies in competitive postcopulatory traits dependent upon dominance status. Dominance in these fish is energetically costly and is dependent upon large body size, and dominant males guard territories to exclude rival males. Smaller males use alternative mating tactics to attempt “sneaky” mating with females and produce more numerous and faster swimming sperm than dominant males. When male charr were forced, by being housed with smaller or larger males, to take “favored” roles as dominant or “disfavored” roles as

subordinate males in an experimental trial, males in the disfavored role rapidly began to produce larger quantities of faster-swimming sperm, demonstrating investment in plastic traits that would enhance fertilization success under intense sperm competition. Here there is a trade-off between body size and sperm production capacity, concordant with the predictions of Parker (1970).

A species of myobatrachid frog, *Crinia georgiana* (Dziminski et al. 2010), demonstrated the link between the level of sperm competition risk and the trade-off in investment in traits to either prevent or win sperm competitions. In populations with the highest densities of males in breeding aggregations, indicating a greater risk of sperm competition for each individual male, males had relatively larger testes and a greater number of sperm stored within the testes. Parker et al. (2013) measured the forearm girth of male frogs in the same populations. Muscular forearms in *C. georgiana* males are used to wrestle other males over territory and to hold on to females during spawning while other males may try to dislodge them. Males from populations with the lowest densities of competing males had the largest forearm girth, as it was only in these low-density populations that males could effectively maintain a territory by wrestling intruders, whereas at higher densities territorial males were overwhelmed, and there was a negative correlation between relative testes size and forearm girth across populations. The prevailing patterns of trait investment across populations in this species provide support for the trade-off between traits used in male-male competitions and traits used in sperm competition.

Inter-specific differences in trait investment and trade-offs have also been found. Two species of Madagascan giant hissing cockroaches, *Aeluropoda insignis* and *Gromphadorhina oblongonota*, were found to differ inter-specifically in body size, weapon size, level of aggression during male-male contests and relative testes size (Durrant et al. 2016). *G. oblongonota*, a large heavily-armored cockroach with large horns on the pronotal shield covering the head, was highly aggressive during staged male-male contests, while *A. insignis* was smaller bodied

with very small horns and lacked aggression during male-male encounters. However, despite *A. insignis* being smaller-bodied than *G. oblongonota*, they had absolutely larger testes, and their testes scaled positively with body size, while *G. oblongonota* had relatively small testes for their size and an allometric relationship that showed testes size was smaller than expected in the largest-bodied males. Weapon size scales with body size, the largest male *G. oblongonota* had larger weapons, while *A. insignis* had absolutely smaller weapons but also a positive allometric relationship between body-size and weapon-size. These patterns of morphological investment indicate that the smaller species does not engage in aggressive male-male contests to access and control females, but is adapted to engage in sperm competition by investing in testes mass, while the larger species appears adapted to fight other males and attempt to control access to females to prevent multiple mating, therefore it does not need to invest in large testes. This example shows Parker et al.'s (2013) predicted trade-off in operation within and between species, with physiological and behavioral consequences for many aspects of an individual's phenotype.

The trade-off between ornaments and armaments, used in male-male pre-copulatory contests, and testes mass has been explored using comparative data (Luepold et al. 2014). The extent to which males are able to monopolize females appears to dictate male investment in either pre-copulatory contest traits or in post-copulatory ejaculate traits. Female monopolizers are defined as species that control access to females, by means such as non-territorial mate guarding or single-male-mating systems in ungulate species. The covariance between pre- and post-copulatory sexual traits gradually shifts from strongly positive to strongly negative with increasing male-male contest competition among taxa. There is a switch from positive or no covariance between armament and/or sexual size dimorphism and testes mass in taxa with little female monopolization; to a negative covariance between these traits in species with high rates of female monopolization. Monogamy was classed as low monopolization

of females due to reduced male-male competition and little polyandry in species such as pheasants and primates, for example, while group and pair spawning minnow species were all classed as low monopolization. Species of dung beetles with high rates of male sneaking behavior and female polyandry were also classed as low monopolization, while species such as pinnipeds which are able to monopolize females through male-male contests had strong negative trade-offs and were classed as high monopolizers. This suggests the potential for a unifying theory for explaining patterns of trait investment and trade-off in species under sperm competition.

## Mate Choice and Cryptic Female Choice

Female choice can operate sequentially or simultaneously with sperm competition, and it is important not to think of the female as passive in the mating process (Eberhard 1996). Females encourage sperm competition by mating with multiple males, but they can also facilitate it further by engaging in rapid and frequent copulations, having capacious sperm storage organs, by not terminating copulations prior to ejaculation, and by providing conditions in the reproductive tract that enable sperm survival. Females can manipulate the amount of sperm transferred by terminating copulations or by having convoluted and very long sperm storage organs that in time digest sperm, rather than allowing it to fertilize. They can also change the direction of sperm movements by muscular contractions or by the beating of cilia lining the reproductive tract. All of these traits allow females to remain active in exercising their choice of mate.

Cryptic female choice, essentially the idea that female choice continues post-copulation just as male competition does, was initially proposed as an alternative to sperm competition. A simple cryptic female choice mechanism is sperm dumping and is observed in spiders, birds and *Drosophila* flies. Domestic fowl (*Gallus gallus domesticus*) hens are able to dump the sperm of unwanted males by ejecting the ejaculate from the

cloaca post-copulation, while this ability has been exploited by the male dunnoek, who peck the female cloaca prior to copulation to induce sperm dumping and remove rival sperm. The female reproductive tract is the arena for sperm competition in internally fertilising species, and it is not inert, but instead has means of transporting sperm and its own physiochemical ecosystem (Eberhard 1996). Hormonal or other alterations of the reproductive tract can favor or disfavor sperm survival or movement. In insects, even if a female is unable to prevent copulation, she can alter her pattern of oviposition such that only a few fertilizations accrue to non-preferred males. If she is unable to redirect sperm away from fertilising the egg, females can reabsorb embryos or abort spontaneously, or provision eggs with differing amounts of nourishing yolk or hormones to favor certain offspring, and therefore males, over others. Evidence for some of the mechanisms by which cryptic female choice may operate is limited (Birkhead and Møller 1998). If it does occur in a widespread manner, it is not necessarily mutually exclusive to sperm competition as an explanation for differential fertilization success.

Traits associated with pre-copulatory male-male competition and post-copulatory sperm competition may not always trade-off against each other, instead they may be positively correlated. Sheldon (1994) proposed the Phenotype-Linked Fertility hypothesis which argued that females use phenotypic indicators of male high quality in mating decisions, such as elaborate plumage or plumage coloration in birds, because they also indicate high quality or more viable sperm. The Sexy Sperm and Good Sperm hypotheses posit similar indirect benefits to females from sperm competition. Sexy Sperm predicts that females that mate multiply will pass the traits that allowed the successfully competing male's sperm to fertilize her ova on to her sons (Curtisinger 1991), while Good Sperm predicts that males that possess competitive sperm also are generally phenotypically superior to unsuccessful rivals, and these traits may be passed on to both sons and daughters (Yasui 1997). All of these hypotheses suggest a vital and active role for

female choice and incorporate the promotion of sperm competition by the female.

A co-evolutionary arms race may occur between males and females, where the males seek rapid and frequent fertilizations and the females seek to avoid having an egg fertilized by more than a single sperm (Arnqvist and Rowe 2013). When more than one spermatozoon penetrates the ova this is called polyspermy. Polyspermy is undesirable because of the conflict between two sets of paternal genes when directing the development of the zygote and most cases of polyspermy end in failure of the embryo to develop. The avoidance of polyspermy leads to a sperm-hostile female reproductive environment that attempts to ensure few sperm reach the ovum in the first place. Because of the co-evolution of sperm competitiveness and female resistance, this leads to selection in males for ever more competitive sperm. The polyspermy theory is in contrast to the Sexy Sperm hypothesis, which makes assumptions about the heritability of sperm characteristics that are not always well supported by evidence (Arnqvist and Rowe 2013). The avoidance of polyspermy also contradicts the Sexy Sperm hypothesis, as the mitochondria, which are one of the determinants of sperm competitiveness, are not inherited by offspring from the father, but rather are maternally inherited, meaning that particular advantage will not be passed on.

## Conclusion

Sperm competition is recognized to be a pervasive and powerful evolutionary force that shapes phenotypes in all sexually reproducing organisms. As soon as there is even occasional polyandrous mating by females, there is the potential for sperm competition. Males have evolved a variety of adaptive physical and behavioral traits to outcompete their rivals, while females have evolved traits of their own to influence the outcomes of competitions in ways that are not always easily observed by researchers, but form a potentially rich area for future studies.

## Definition

Spermatogenesis is the process by which an animal that exhibits sexual reproduction produces spermatozoa from spermatogonial stem cells (SSCs) through a series of mitotic and meiotic cell divisions.

## Spermatogenesis trough the animal life cycle

Spermatogenesis is the process by which cells known as diploid (2n) male germline cells undergo a series of mitotic and meiotic divisions. These divisions culminate in a complex and well-orchestrated process of differentiation, which gives rise to haploid (n) male gametes. Some of these gametes will participate in the process of fertilization and production of new individuals in animals that exhibit sexual reproduction (Hess 1999). This elaborate process involves several genetic and epigenetic factors of germ cells and other associated somatic cells, as well as the environmental factors to which these cells are exposed. The spermatogenesis process occurs inside what is known as germ tissue (Handel and Schimenti 2010). Germ tissue can be organized into a simple cluster of cells in the medial portion of the animal's body cavity or as cordonal or cystic organs in the abdominal cavity. Some vertebrates, such as birds and mammals, have their germ tissue organized in the form of tubular structures called seminiferous tubules, which are stored inside the testicles (Hess 1999).

In mammals, the events that characterize the development and differentiation of germline cells start early in the embryonic life cycle. In some individuals, primordial germ cells (PGCs), or gonocytes, follow the oogenesis pathway, while in others they follow the spermatogenesis pathway. Early stages of male-specific germ cell development involve several coordinated processes, including the active maintenance of pluripotency followed by the precisely timed loss of pluripotency, the remethylation of the genome and upregulation of male-specific markers, the locking down of male differentiation, and the suspension of cell division. Genes that are key

regulators of these processes have been identified and include the fibroblast growth factor 9 (*Fgf9*), Nodal, Cripto, Activin, Prostaglandin D2 (*Pgd2*), and Nanos2. Many of these factors are involved in more than one of the aforementioned process. The balance between the presence and absence of retinoic acid (RA) is also important in this sex determination process (Spiller et al. 2017; Fig. 1).

These PGCs remain mitotically quiescent until birth in mice, whereas in humans, they do not enter total quiescence but do exhibit varying proliferative activity (Manku and Culty 2015). PGCs that reach the basement membrane form the spermatogonial stem cell (SSC) population and give rise to the differentiating spermatogonia of the first cycle of the seminiferous epithelium (Yoshida et al. 2006). However, this differentiation process does not start until the animal reaches sexual maturity. The physiological event that

guarantees its occurrence is the SSC's self-renewing mechanism, which itself occurs through successive and well-balanced mitotic divisions. This self-maintenance of SSCs in the germ tissue is governed by the existence of a specific microenvironment through the actions of somatic cells known as Sertoli cells. Sertoli cells exhibit broad gene expression plasticity and rely primarily on levels of FSH (produced by the pituitary gland) and testosterone (produced by testicular Leydig cells) to exert a paracrine control over the proliferative activity of the SSCs. Exit from these self-renewing state and consequent differentiation commitment are the first steps on the long road of spermatogenesis, and they take place when animals reach sexual maturity (Mäkelä and Toppari 2017; Fig. 1).

The beginning of the spermatogenesis process, which is characterized by the onset of SSC

**Spermatogenesis, Fig. 1** Schematic view of the spermatogenesis process. Representation of embryo phase is based on mice sex determination (inspired by Spiller et al.

2017). Representation of puberty, adult, and aged phase is based on human spermatogenesis (inspired by Mäkelä and Toppari 2017) (*dpc* days postcoitum)

differentiation, is also controlled by Sertoli cells. The entire physiology of adult testes is also controlled by mechanisms of activation and repression of certain genes (some of which are located on the sex chromosomes and others are located on the autosomes), as well as by complex mechanisms of gene expression control mediated by small noncoding RNAs (Lopes and Roelen 2010). Mammalian spermatogenesis is classically divided into three phases: (1) the mitotic (proliferative) phase; (2) the meiotic phase; and (3) the spermiogenic phase (Mäkelä and Toppari 2017):

1. *Mitotic phase*: Stem  $A_{\text{dark}}$  spermatogonia (while still true SSCs) (2n) rarely divide through mitosis (the self-renewal mechanism). When this division produces differentiated  $A_{\text{pale}}$  spermatogonia (2n), the process of spermatogenesis begins. These  $A_{\text{pale}}$  spermatogonia can go through a limited number of mitotic divisions for their own self-renewal until a mitotic division produces type B spermatogonia (2n). Type B spermatogonia divide through mitosis and differentiate into primary spermatocytes (2n).
2. *Meiotic phase*: Primary spermatocytes are cells that undergo the first meiotic division. Meiotic division consists of a series of events classified as Prophase I, Metaphase I, Anaphase I, and Telophase I. Prophase I is the stage that includes meiotic recombination, one of the most important genetic events in spermatogenesis: it is the result of the crossover between paired regions of homologous chromosomes (Hess 1999). Secondary spermatocytes (n) emerge as a result of the first meiotic division. These cells have a short lifespan because they quickly divide during the second meiotic division, giving rise to round spermatids (n) (Mäkelä and Toppari 2017).
3. *Spermiogenic phase*: Round spermatids will undergo a process called spermiogenesis, which involves increased chromatin condensation, core compaction, cytoplasmic remodeling, and epigenetic profile modification, which results in cells known as elongated spermatids (n) (Peruquetti 2015; Fig. 1). Mature

elongated spermatids are released into the tubular lumen and are stored in the epididymis. They are externalized during the mating process.

Several studies have shown that male endocrine function decreases with age, as does the quality of seminal parameters such as number and viability of sperm (Angelopoulou et al. 2013; Fig. 1). Nevertheless, barring any pathological factors, spermatogenesis is a process that persists for many years, which makes it clear that males have the ability to produce viable offspring until very late in their life cycle.

## Spontaneous Recovery

D. A. Williams  
University of Winnipeg, Winnipeg, MB, Canada

## Synonyms

[Return of fear](#)

## Definition

*Spontaneous recovery* occurs when a previously learned response returns after a time interval following extinction.

## Introduction

First described by Pavlov (1927), the demonstration of spontaneous recovery in the laboratory requires a three stage experiment, conditioning, extinction, and test. In the conditioning stage, a conditioned stimulus (CS, such as a ticking metronome) is repeatedly paired with the unconditioned stimulus (US, such as food) until a vigorous conditioned response (CR, such as salivation) comes through associative learning to evoked by the CS. When the US is subsequently withheld in the extinction stage, the CR declines in magnitude and probability because the CS is no longer paired the US. At test, assuming a sufficiently long period of time has elapsed, the first presentation of the CS is likely to evoke a much larger CR than it did on the final trial of extinction. The CR is said to have *spontaneously recovered* because the passage of time without any experimental manipulation caused the CR to reappear. As one might suspect, additional test presentations of the CS without the US normally produce rapid re-extinction, whereas re-pairings of the CS and US normally produce rapid reacquisition.

Spontaneous recovery is a result rather than an explanation. But, as a result, it has important theoretical and applied implications. Its occurrence stimulated the view that extinction results in something new being learned. The old learning is not erased leaving nothing. This idea can be traced to Pavlov (1927). Suppression rather than loss seemed to him to be the most straightforward explanation of why CR recovery is possible after extinction. According to Pavlov, extinction procedures lead to a loss of responding, but the first learned CS-US association is not lost. Rather, the normal behavioral effects of CS-US association are limited by the development of inhibition over the course of extinction. Pavlov maintained a CS centered view of conditioned inhibition in

which the learned neural inhibition acquired in extinction gradually faded over time. A modern neuroscientist might be more likely to say that spontaneous recovery tells us that conditioning and extinction memories coexist in distinct neural connections and are activated independently based on a number of factors. Both would agree that something new is learned in extinction. One critical piece of support for new learning accounts is that pharmacological blockade of a special type of neural receptor involved in learning process (*N*-methyl-D-aspartate, or the NMDA receptor) undermines extinction (Falls et al. 1992). This suggests that new learning is happening during extinction in the absence of the drug. Thus, declines in behavior do not necessarily imply a weakened CS-US association. The later discovery of “extinction neurons” in the amygdala (Herry et al. 2008), which fire in extinction but not conditioning, is an intriguing result in line with Pavlov’s thinking.

Although spontaneous recovery rarely causes CR levels returning to pre-extinction levels, the ubiquity of spontaneous recovery has profound applied implications. The spontaneous recovery of fear CRs, in particular, raises many questions relevant to the treatment of anxiety disorders. Exposure therapy conducted in the clinic is designed to help people confront their fears in a safe situation. Feared stimuli are repeatedly presented in the absence of any aversive event in the hopes this will diminish fear. Putting aside the topic of anxiety disorders for the moment, we can ask the following questions (1) does the passage of time cause inhibition to dissipate leading to spontaneous recovery, as Pavlov (1927) theorized, or does extinction learning remain but is somehow more poorly expressed, (2) what conditions prevent spontaneous recovery, and (3) is the conditioning memory is partially erased by extinction causing incomplete spontaneous recovery? Answers to these questions are important because potential treatments are informed by an understanding of the processes responsible for spontaneous recovery. The partial NMDA agonist D-cycloserine (DCS), for example, has been tested in humans (Myers et al. 2011) to determine if it aids the consolidation of extinction learning, and

thereby minimizes the spontaneous recovery of fear.

## Does Inhibition Fade?

Does inhibition fade over time as Pavlov (1927) hypothesized? Few would agree the data merit this assumption. Devenport (1998) formulated the temporal weighting rule in which memories were weighted less heavily over time as they became more remote. The temporal weighing rule was inspired by accounts of foraging behavior in animals. Immediately returning to a formerly rich patch of food after it has been thoroughly exploited is not a good strategy. However, a later return after the patch has a chance to replenish itself might pay dividends. The weighting rule provides a natural account of increasing levels of spontaneous recovery over time since extinction. When the extinction memory is fresh, it is relatively more likely to be assessed than the earlier memory of a rich patch. This formulization does not assume learned inhibition is the process leading to extinction, nor does it assume that anything has faded. It assumes two relatively permanent memories of conditioning and extinction are formed and the relative ease of retrieval of these memories changes over time.

## Conditions Favoring Spontaneous Recovery

What conditions favor the occurrence of spontaneous recovery? Any theory of spontaneous recovery must explain the basic finding that spontaneous recovery gradually increases over time. Being too tired to respond might be expected to depress responding in extinction, and a 1 day rest might permit responding to return. However, this explanation does not explain why of two extinguished CSs in the same animal, the one extinguished yesterday supports less spontaneous recovery than the one extinguished over a week ago (Rescorla 2004). The response is common to the two CSs in test and cannot differentiate between them. The results of this last experiment

should be interpreted with caution. One should not conclude that performance factors don't matter at all. They just can't be the primary explanation.

One factor known to reduce spontaneous recovery is delaying the time of extinction until many days after the last conditioning session. Devenport's rule predicts that spontaneous recovery should be minimal when the interval between conditioning and extinction is maximal, making extinction the much more recent memory on a relative basis. It is not obvious how CS inhibition, developing in extinction and then fading, could handle such a result. Extinction trials scheduled after the point of the cessation of the CR also reduce spontaneous recovery. Called "extinction beyond zero" by Pavlov (1927), it is also known as massive extinction. The number of sessions of extinction per se is also an important variable. Each inter-session interval permits spontaneous recovery to reoccur, and then be eliminated with additional unreinforced trials.

A change in context from extinction to test can greatly enhance the recovery of responding. This phenomenon is so robust it has earned its own name, *renewal*. Renewal refers to increased recovery when the CS is tested in a different environment than it was extinguished. The classic case is ABA renewal. The nomenclature used describes the physical locations of the three successive stages of a standard spontaneous recovery experiment, conditioning (in Context A), extinction (in Context B), and test (a return to Context A). Other types of renewal include AAB and ABC. Extinction in multiple contexts gradually reduces the level of spontaneous recovery seen when each context is experienced for the first time.

The importance of context has led to a popular theory about how spontaneous recovery is best explained. Bouton and colleagues (e.g., Bouton et al. 2006) suggest that time acts like the presence of a physical context. As time passes in our lives, we experience many new events while other events continue to reoccur. Events present at the time of extinction (like physical contexts) may aid in the retrieval of the extinction memory if they are also present

at test. If these events are no longer present, spontaneous recovery may occur in the absence of extinction reminder cues. More formally, extinction is said to produce a new CS  $\rightarrow$  no US association that hinders responding triggered by the previously acquired CS  $\rightarrow$  US association. Because the new CS  $\rightarrow$  no US association is contradictory, its retrieval is more contextually and temporally limited than the first-learned CS  $\rightarrow$  US association. A switch out of the extinction context and/or increasing time since extinction should make it more likely that spontaneous recovery will occur. One of the more interesting predictions of this account is that reacquisition might be retarded rather than facilitated if extinction cues are very strong. Neurons in the infralimbic region in the prefrontal cortex seem to play a role similar to the one described by Bouton et al. (2006). If inactivated, they very nearly eliminate the recall of extinction the day after extinction, but do not prevent it from happening in the first place (Quirk et al. 2006).

## Weakened Associations

Not all theories assume that CS-US associations are left intact in extinction (Delamater and Westbrook 2014). That spontaneous recovery is rarely complete is the single most obvious reason to think that extinction might involve a partial loss of the CS-US association. Skinner (1938) assumed permanent response weakening occurs in extinction, and some aspects of the original learning experience are spared. He speculated that stimuli from the beginning of the session might be protected from extinction because all responding had yet to be removed at that point. Estes (1955) stimulus sampling theory maintains only a portion of the elements of the CS are sampled on each trial, and thus elements not sampled at the time of extinction may later be sampled at test. As they have yet to undergo extinction, spontaneous recovery might be expected. Even if some of the old learning is spared in the manner suggested by Skinner and Estes, this does not imply old associations are weakened.

## Spontaneous Recovery in Instrumental Learning

Spontaneous recovery is also observed in instrumental or operant conditioning. Pressing a lever can be arranged in the laboratory to produce a valuable commodity, such as food pellet reinforcer. When the reinforcer that normally followed that response is withheld, extinction occurs. However, the response may spontaneously recover over time in the absence of the chance to respond. Both Todd (2013) and Rescorla (2004) have argued that instrumental extinction is best characterized by the idea that previously reinforced responses are inhibited. This account holds stimuli present at the time of extinction must be present at test to prevent spontaneous recovery.

## Conclusions

Most researchers are in agreement that spontaneous recovery implies the original CS-US association survives extinction to some extent. They would also agree that spontaneous recovery implies some of the mechanisms accounting for within session declines in responding may not operating at the time of test, shifting the focus of attention to a failure of the retention of extinction to explain spontaneous recovery. A number of mechanisms have been proposed, including many processes not even mentioned in this brief entry. Many of these mechanisms are complementary so embracing one does not mean the other is wrong. For example, the mechanisms described by Skinner and Estes are clearly incomplete and might not be wrong, but Pavlov (1927) was certainly correct in asserting that some new learning occurs in extinction that covers up the old learning, leading to spontaneous recovery.

## Introduction

Of the currently extant nonavian Reptilia, the order Squamata is by far the largest. At the time of this writing, this order is represented by 10,221 described species. This group includes some of the most recognizable of reptiles, the lizards and snakes. Within the lizards, diets vary widely from strict herbivores to purely carnivorous forms.

Some well-known examples on either end of the spectrum are the iguanas in the family Iguanidae (herbivores) and the generally large, among lizards, carnivorous (or mostly so) monitor lizards (family Varanidae). The Serpentes (snakes) are all some variation of carnivore (insectivorous, oophagous, carnivorous), with most having lightly constructed skulls that appear to be formed by series of struts and ligaments that allow for the consumption of prey larger than the size of their heads in a number of taxa. Most famously, this skull construction allows snakes like the giant boas and pythons to swallow prey as large as antelope or deer. As impressive as these prey items are, the highest ratios of prey/predator mass has been observed in vipers and pipesnakes, with some consuming prey equal to or exceeding their own body mass. There are myriad adaptations among the various families of Squamata related to feeding and diets. This chapter aims to review in a generalized sense the diets and notable adaptations of the various groups of squamates from a phylogenetic viewpoint. It is not intended to be an exhaustive review of all diets or dietary adaptations within Squamata. The taxonomy follows the online Reptile Database ([www.reptile-database.org](http://www.reptile-database.org)) and the phylogeny is that of Pyron et al. (2013).

## Food and Feeding Habits of Snakes (Serpentes)

Within Squamata, the snakes are among the most recognizable due to their limbless condition. While there are numerous forms of limbless lizards, those that are classified within the Serpentes (or Ophidia) are the most derived. There are over 3,700 currently recognized species of snakes worldwide and they fill a number of terrestrial, arboreal, and aquatic predatory niches.

While there are no herbivorous species of snakes, diets can vary widely from consuming termites up to large mammalian prey. There are even reports of snakes consuming carrion. We will review the diversity of snakes and their general diets according to their phylogeny. Dietary information for the taxonomic groups largely adheres to information presented in Greene (1997) unless otherwise noted.

**The “Blindsnakes”:** While not a truly monophyletic group, the snakes in the following families are collectively referred to as blindsnakes or threadsnakes: Anomalepididae, Leptotyphlopidae, Gerrhopilidae, Xenotyphlopidae, and Typhlopidae. They are Pantropical including Madagascar and Australia with some reaching temperate regions. These snakes have unique skull morphologies and dentitions that allow for fossorial lifestyles and a diet of ants and termites, including their eggs and larvae.

**South American Pipesnakes (Aniliidae):** This family currently includes a single species, the South American Pipesnake (*Anilius scytæ*), which feeds primarily on long-bodied prey such as caecilians, amphisbaenians, other snakes, and eels.

**Neotropical Dwarf Boas (Tropidophidae):** This family includes the Caribbean and South American genus *Tropidophis* and the eyelash boas in the genus *Trachyboa*. These snakes are all typically less than 1 m in length. All species feed primarily on amphibians and lizards at all life stages.

**Spinejaw Snakes (Xenophidiidae):** This family of snakes was only recently discovered and are poorly known. There are two species described (*Xenophidion acanthognathus* and *X. schaeferi*) from Borneo and peninsular Malaysia. They are believed to feed on scincid lizards.

**Round Island Boas (Bolyeriidae):** The single extant species in this family, the Round Island Ground Boa (*Casarea dussumieri*), has a unique hinge between the two component bones of the maxillary which allows it to pull the anterior segment of each maxilla downward, an adaptation that appears to aid in holding prey. *Casarea dussumieri* feeds primarily on geckos and skinks.

**Calabar Burrowing Boa (Calabariidae):** The Calabar Burrowing Boa (*Calabaria reinhardtii*) of western Africa is the only member of this family and feeds on nestling rodents concealed in leaf litter and low vegetation.

**Boas (Boidae):** The family Boidae is rather diverse and speciose. Members of this family are found on all continents except Antarctica and Australia (Graham Reynolds and Henderson 2018). Most are dietary generalists and ambush predators that can go long periods of time between

meals. Unless otherwise noted, all information regarding the Boidae adheres to that presented in Greene (1997) and Henderson and Powell (2007).

The boas in the subfamily Boinae are restricted to the neotropics. This subfamily includes heavy-bodied generalists like the boa constrictors (*Boa*) and the world’s heaviest and one of the longest snake species, the Green Anaconda (*Eunectes murinus*). These large, stout snakes are powerful constrictors that prey on a wide variety of vertebrate prey at all life stages. Of somewhat more slender build are the rainbow boas and Caribbean boas (*Chilabothrus* and *Epicrates*), some of which are highly arboreal. All feed primarily on small mammals as adults, although some of the Caribbean species include more lizards in their diets, especially when young. The most specialized to an arboreal lifestyle in this family are the tree boas in the genus *Corallus*. These snakes have elongated teeth that allow for a stronger grip on their predominantly mammalian and avian prey captured in the trees, with the two species of emerald tree boa (*C. batesii* and *C. caninus*) having especially formidable looking teeth. Additionally, they have well-developed infrared receptors situated in pits along the upper and lower lips that presumably aid them in visualizing endothermic prey.

Members of the subfamily Ericinae (sand boas) and some of the Ungaliophiinae (bromeliad, rosy, and rubber boas) are found in temperate regions of Eurasia and North America, respectively. The African and Eurasian sand boas of the Erycinae feed on small rodents, lizards, and occasionally birds. Of the Ungaliophiinae, the small bromeliad boas (genera *Exiliboa* and *Ungaliophis*) of Latin American forests prey upon amphibians and lizards. The Rosy Boa (*Lichanura trivirgata*) occupies rocky chaparral and deserts of the American Southwest while the Rubber Boa (*Charina bottae*) occurs mostly in the moist forests of north western North America. Both species feed primarily on rodents and small birds.

The Pacific boas in the genus *Candoia* are restricted to the Solomon Islands, New Guinea, and several other islands in the south Pacific. All feed largely on lizards as juveniles while transitioning to a primary diet of small mammals as adults.

**Dwarf Pipesnakes (Anomochilidae):** The snakes in the genus *Anomochilus* are found in Borneo, Sumatra, and peninsular Malaysia. These snakes are very poorly known with little data on their natural history.

**Asian Pipesnakes (Cylindrophiiidae):** Asian pipesnakes (*Cylindrophis*) are burrowers that specialize in feeding on caecilians, eels, and other snakes. These snakes can consume prey equal to their own mass. Unlike many snakes that typically demonstrate high prey/predator mass ratios, pipesnakes have relatively small gapes (Hampton 2018), which limit them to consuming long, cylindrical prey items that are of similar or smaller diameter to themselves.

**Shield-tailed Snakes (Uropeltidae):** This family consists of over 50 species in seven genera all found in India and Sri Lanka. Shield-tailed snakes are fossorial and feed on earthworms.

**Asian Sunbeam Snakes (Xenopeltidae):** So-named for their smooth, highly iridescent scales, the two species of Asian sunbeam snakes (*Xenopeltis hainanensis* and *X. unicolor*), have folding teeth and feed on skinks as well as frogs and rodents.

**Neotropical Sunbeam Snakes (Loxocemidae):** Sometimes referred to as the “burrowing python,” the single species in this family (*Loxocemus bicolor*) has an upturned snout which it utilizes for digging, including the excavation of lizard and turtle eggs. They also feed on lizards and rodents.

**Pythons (Pythonidae):** The pythons are restricted to Africa, Asia, and Australasia. Unless otherwise noted, all information regarding the Pythonidae largely follows Greene (1997) and Henderson and Powell (2007). They range in size from the under 1-m Anthill Python (*Antaresia perthensis*) to the world’s longest snake species, the Reticulated Python (*Malayopython reticulatus*), which may reach 10 m in length. All pythons are powerful constrictors and most species consume endothermic prey, although the Australian pythons in the genus *Aspidites* often prey on squamates. Additionally, most pythons have exceptionally large gapes and loosely constructed skulls allowing them to consume prey several times larger than their heads

and the thickness of their bodies. Pythons are well-known for going long periods in between such hefty meals. With the exception of *Aspidites*, all pythons are equipped with infrared receptors situated in a series of deep pits in the labial scales about the mouth that function as pinhole cameras to visualize their surroundings and, presumably, specifically endothermic prey.

**Elephant Trunk Snakes (Acrochordidae):** Also known as file snakes, these heavy-bodied fully aquatic snakes are only found in Australasia. These snakes feed primarily on fish, with *A. granulatus* appearing to feed largely on gobies and crustaceans while the other two species; *A. arafurae* and *A. javanicus*, feed largely on eels, catfish, and other freshwater fish. Similar to the pythons, these snakes have exceptional gape limits and can consume very large prey in comparison to their body size (Shine 1986).

**Xenodermatidae:** This family consisting of 18 species within six genera are found in southeastern Asia. These poorly known snakes are fossorial and feed on frogs.

**Slugsnakes (Pareatidae):** These snakes generally feed on terrestrial mollusks, pulling snails from their shells using needle-like teeth and alternating movements of their elongated mandibles. One species, the Blunt-headed Treesnake (*Aplopeltura boa*) feeds on lizards.

**Vipers and Pitvipers (Viperidae):** The vipers and pitvipers are found on every continent except Antarctica and Australia. All have mobile, anteriorly placed large hollow fangs for delivering venom. Much of the information regarding the vipers and pitvipers is summarized from Greene (1997) and Schuett et al. (2002) unless otherwise noted in the text. They are largely terrestrial, though a number of species have taken to an arboreal lifestyle. Despite the high species diversity within this family (347 species to date), only the Cottonmouth (*Agkistrodon piscivorus*) of the southern United States has adopted a largely semi-aquatic lifestyle and aside from some of the African night adders (*Causus*), none of the Viperidae have special adaptations for burrowing. The two largest taxonomic groups within this family are the Old World vipers and adders (Viperinae) and the pitvipers (Crotalinae). Similar to some of the

boas and pythons mentioned previously, pitvipers have infrared receptors located in pits on both sides of the head between the eye and nostril. The third group, the Azemiopinae, is represented by two species within the genus *Azemiops*. These snakes from the highlands of Myanmar, southern China, and Vietnam are poorly studied, with scant information on their diet.

The Viperinae are restricted to Africa, Asia, and Europe. Most of the Eurasian vipers and adders (*Macrovipera*, *Montivipera*, *Vipera*) are a meter or less in length, although some species like the Russell's Viper (*Daboia russelli*) may reach nearly 2 m. They occupy mostly temperate regions. They mainly feed upon insects, frogs, and lizards as juveniles while typically consuming mammals as adults. The strictly African members of the genus *Bitis* are particularly stout snakes. There are examples of Gaboon Vipers (*Bitis gabonica*) nearing 2 m in length and exceeding 10 kg in mass. These exceptionally large vipers have been documented to predate upon a range of mammals, including antelope. Smaller members of this genus like the Perringuey's Adder (*B. peringueyi*) stay well under a meter long and feed on small mammals and lizards. The several species of saw-scaled vipers (*Echis*) live in arid regions of Africa, middle Asia, and India. They feed on arthropods, birds, lizards, and small rodents (Richards et al. 2012). The bush vipers in the genus *Atheris* are mostly arboreal, relatively small (under 1 m) species that feed on lizards, frogs, birds, and small mammals.

The pitvipers (Crotalinae) are widely distributed throughout the New World and Asia. They include a diversity of forms from relatively slender arboreal forms (e.g., *Bothriechis* in the neotropics and *Trimeresurus* in Asia) to heavy-bodied forms like the rattlesnakes (*Crotalus* and *Sistrurus*) of the Americas. Pitvipers overall are dietary generalists feeding on a variety of invertebrate, amphibian, squamate, bird, and mammalian prey. Of these generalists, the Cottonmouth (*Agkistrodon piscivorus*) is perhaps the most extreme example, eating small turtles and even carrion. Like other viperids, pitvipers have large gapes allowing them to consume very large prey items in relation to their size. A Sidewinder

Rattlesnake (*Crotalus cerastes*) from the southwestern United States reportedly consumed a lizard with a mass that was approximately 115% that of the snake itself (Webber et al. 2016).

#### **Australasian Watersnakes (Homalopsidae):**

Homalopsidae includes the Australasian watersnakes. These aquatic snakes inhabit freshwater or marine habitats and have grooved rear fangs to deliver venom. Most feed on fish, but the White-bellied Mangrove Snake (*Fordonia leucobalia*) is an exception in two respects: it preys on crustaceans and is unique among snakes in that it consumes prey piecemeal – pinning the prey to the substrate with the body and dismembering larger prey so that it may be consumed.

**Lamprophiidae:** This very large (322 species) family is mostly found in Africa, western Asia, and southern Europe. One of the more speciose groups, the Psammophiinae is rear-fanged, mostly slender, diurnally active snakes with most species occurring in Africa and western Asia, the exception being the Montpellier Snake (*Malpolon monessulani*) from southern Europe. They predate largely upon lizards, although the beaked snakes (*Rhamphiophis*) have angled snouts that assist with excavating subterranean prey, including Naked Mole Rats (*Heterocephalus glaber*). Several members of this group have specializations for eating skinks similar to those seen in a number of other unrelated taxa. Atractaspidines are commonly known as stiletto snakes or burrowing asps. They are known from Africa and the Middle East. While the genus *Atractaspis* has movable front fangs similar to viperids, the genus *Homoroselaps* has fixed front fangs more akin to those of the Elapidae. These burrowing snakes feed primarily on elongate reptiles and other vertebrates as well as earthworms. The Aparallactinae occur in sub-Saharan Africa, are rear-fanged, and feed on a variety of prey including centipedes, squamates, frogs, and rodents. The Pseudaspidinae include the African mole snakes (*Pseudaspis*), Asian mock vipers (*Psammodynastes*), and the African forest snakes (*Bufo*). Mole snakes primarily eat small mammals, mock vipers mostly lizards and frogs, and the forest snakes feed on aquatic vertebrates. Lamprophiinae includes nearly 80 species which

are mostly African in distribution. This group includes the mostly lizard eating wolfsnakes (*Lycophidion*), the primarily snake eating filesnakes (*Gonionotophis*), and the rodent and lizard eating African housesnakes (*Boaedon*, *Lamprophis*) among many other taxa (Paterson 2018). The last group within Lamprophiidae is the Pseudoxyrhophiinae containing 90 species. This group is inclusive of a number of notable taxa. A few are the aptly named African Slug-eaters (*Duberria*), the Madagascan Leaf-nosed Snake (*Langaha madagascariensis*) which specializes in feeding on lizards, *Liophidium* which have folding teeth and specialize on skinks, the Madagascan hognose snakes (*Leioheterodon*) which are dietary generalists that also predate upon reptile eggs, and *Compsophis* which feeds on aquatic vertebrates.

**Cobras and Their Relatives (Elapidae):** The family Elapidae consists of some of the world's deadliest snakes. All species are venomous and have fixed fangs in the front of their mouths. They may be found on every continent but Antarctica and are incredibly diverse with over 370 species described to date. Included in this family are cobras, kraits, mambas, coral snakes, sea snakes, taipans, and others. They live in most habitat types and in the case of the sea snakes, marine environments. They range in size from under a meter for some of the brightly colored coral snakes to over 5 m for the King Cobra (*Ophiophagus hannah*), which is the world's longest venomous snake. As a whole, they are dietary generalists with relatively small gapes even for the largest species. As such, many specialize in long-bodied prey like caecilians and other snakes.

Cobras are highly diverse and widespread in Africa and Asia with several species attaining lengths of 3 m or more. They have cosmopolitan diets, feeding on a variety of vertebrates including mammals, birds, amphibians, other reptiles, and even slow-moving fish (e.g., *Naja melanoleuca*). King Cobras (*O. hannah*) are generalists but primarily consume other reptiles, mostly snakes. The semifossorial African coral cobras (*Aspidelaps*) may be habitat specialists, but are dietary generalists feeding on frogs, lizards and their eggs, rodents, and even termites. The water cobras

(*Naja [Boulengerina]*) live semiaquatic lifestyles and feed primarily on fish. The Rinkhals (*Hemachatus hemachatus*) feeds mostly on toads. The mambas (*Dendroaspis*) can reach lengths of 3 m or more in the case of the Black Mamba (*D. polylepis*), while the other species are around 2 m. They all feed primarily on mammals and birds and lead arboreal lifestyles. The African gartersnakes (*Elapsoidea*) feed mainly on snakes, lizards, and their eggs, but have been known to consume mammals with one species perhaps specializing on caecilians.

Australasian elapids are highly diverse, with stout-bodied small species like the death adders (*Acanthophis*) and slender fast-moving taipans (*Oxyuranus*) that can exceed 2 m long. As with other elapids, they have highly varied diets and consume lizards, mammals, and birds, though a few smaller species are more specialized. An example is the Australian Bandy-bandy (*Vermicella annulata*) which eats only blind snakes. Unlike many elapids, which tend to be more active predators, the death adders (*Acanthophis*) resemble vipers in overall appearance and adopting a sit-and-wait hunting mode to predate upon lizards, small mammals, and birds.

The coral snakes of Asia and the New World are quite similar. They are incredibly diverse in the New World, being found mostly in the neotropics but also ranging into more temperate zones (e.g., *Micrurus fulvius*). Most are a meter or less, although the Aquatic Coral snake (*M. surinamensis*) can be over 1.5 m long. As a whole, coral snakes feed mostly on elongate prey like snakes, limbless lizards, caecilians, and eels in the case of the Aquatic Coral snake (*M. surinamensis*). One species, *M. hemprichii*, is notable for feeding on onychophorans. The Asian coral snakes are fossorial and specialize in eating other snakes.

The kraits (*Bungarus*) and sea kraits (*Laticauda*) are found only in tropical Asia. *Bungarus* feed largely on fish but some species also feed on frogs as well as other snakes. The sea kraits in the genus *Laticauda* are generally found in or near coral reefs and feed largely on eels.

Seasnakes may be found in the tropical waters of the Indian and Pacific Oceans. They are highly adapted for a marine lifestyle and never leave the

water. Generally, they forage for prey in holes or crevices as opposed to active pursuit in open water. They feed on a variety of marine organisms, although fish are the largest dietary component for nearly all species. One of the most specialized of the seasnakes is the Turtle-headed Seasnake (*Emydocephalus annulatus*). This species eats only the eggs of bottom-dwelling fish like gobies and blennies. They have pointed snouts, specialized muscles possibly related to suction feeding, and have reduced toxicity of their venom.

**Colubridae:** The largest family of extant snakes is the Colubridae. They are globally distributed excluding Antarctica although they do reach the Arctic Circle. In an effort to simplify what is an exceptionally large, diverse group of snakes, Old World and New World colubrid snakes will be treated separately. Additionally, this is not meant to be an exhaustive review of all snakes within this family; however, it is intended to highlight notable groups or species.

**Old World Colubridae:** The small snakes of the subfamily Calamarinae are found in southern Asia and demonstrate adaptations to a burrowing lifestyle. They feed primarily on earthworms and insect larvae, although some are known to eat skinks.

The Sybiniophiinae, or hinged-teeth, snakes include two genera (*Sibynophis* and *Scaphiodontophis*) that are closely related yet globally disjunct (*Sibynophis* in southern Asia and *Scaphiodontophis* in Central and South America). Both have unique hinged maxillary teeth and feed primarily on hard-bodied prey like skinks (Campbell 1998; Savitzky 1981).

The subfamily Grayiinae includes a handful of species in the genus *Grayia*, all found in Africa. They feed primarily on fish and frogs.

The Pseudoxenodontinae are found in Southern Asia. Snakes in the genus *Pseudoxenodon* feed mostly on frogs and lizards while *Plagiopholis* feed on earthworms.

The subfamily Colubrinae is incredibly diverse in the Old World. Some notable genera include the Eurasian dwarf snakes of the genus *Eirenis* that feed on a range of prey items including small arthropods and lizards, the lizard eating Asian

“flying” snakes in the genus *Chrysopelea* which are known for flattening their bodies after springing from the trees and travelling to the ground or other trees by controlled gliding, and the Old World racers and ratsnakes (*Ptyas*, *Gonyosoma*, and *Elaphe*) which have highly varied diets with some getting quite large (e.g., *Ptyas mucosa* reaching over 2 m).

A large number of Asian colubrinae are rear-fanged. These include the highly diverse kukrisnakes (*Oligodon*) which are all under 1 m in length and feed on a wide variety of prey including arthropods, mammals, frogs, lizards, birds, and their eggs. The moderately sized to large slender-bodied snakes in the genus *Boiga* are often referred to as cat snakes. The most famous and largest of these is the Brown Treesnake (*B. irregularis*), which is naturally found in New Guinea, the Solomons and surrounding islands, and northern Australia was accidentally introduced to the island of Guam, where it has caused major ecological damage as a generalist predator on the island’s fauna. The Asian vinesnakes of the genus *Ahaetulla* have elongate snouts and very slender bodies. These snakes have eyes that allow them stereoscopic vision that may help in hunting lizards, which most species specialize in.

In Africa, Colubrinae includes two of the few rear-fanged snakes that have been known to cause fatal envenomations in humans: the Boomslangs (*Dyspholidus*) and Twigsnakes (*Thelotornis*) which feed primarily on birds and lizards. While many snakes feed on bird or reptile eggs, African egg-eating snakes (*Dasypeltis*) are the most highly adapted for ingesting bulky items like eggs, even having specialized ribs that allow the snakes to crack the eggshells once consumed so they can ingest the contents. Once the contents are consumed, the snake typically regurgitates the egg shell. The leaf-nosed (*Prosyma*) and shovel-nosed snakes (*Lytorhynchus*) utilize upturned rostral scales to excavate buried lizards and their eggs. This trait and behavior is also seen in some New World colubrinae.

Snakes within the Old World Natricinae includes a number of terrestrial and semiaquatic taxa in Eurasia, Africa, and Asia. They are overall

small snakes (1 m or less). The Eurasian grass snakes (*Natrix*) are semiaquatic and feed primarily on fish and amphibians. The bite of two species of keelbacks in the Asian genus *Rhabdophis* are considered potentially fatal to humans. These snakes may be terrestrial or aquatic and feed mainly on fish and frogs, although some are known to have more variable diets including lizards, rodents, and birds, as well.

**New World Colubridae:** The New World has a very high diversity of colubrid snakes that occupy highly diverse niches. For the colubrine snakes, the North American ratsnakes (*Pantherophis*), pine and gopher snakes (*Pituophis*), and kingsnakes (*Lampropeltis*) are powerful constrictors. Most ratsnakes are semiarboreal while the kingsnakes are typically terrestrial or fossorial. Pine and gopher snakes are typically terrestrial and semifossorial, although some gopher snakes show semiarboreal tendencies. Ratsnakes and the pine and gopher snakes typically feed on mammalian or avian prey including their eggs. The kingsnakes often feed on rodents and other squamates. They are famous for their eating of other snakes, particularly venomous species. These are also among the most popular of snakes to be maintained in captive conditions. The New World racers and whipsnakes (e.g., *Coluber*, *Drymobius*, and *Mastigodryas*) are aptly named as they are diurnal, fast moving snakes. They have highly variable diets ranging from insects and smaller vertebrates when young to large insects, lizards, other snakes, small mammals, and birds as adults. Another genus of New World snakes, the cribos and indigo snakes (*Drymarchon*) may get quite large (over 3 m in some species). Similar to racers and whipsnakes, they are diurnal, highly active, and have incredibly varied diets. In the southeastern United States, the Eastern Indigo Snake (*D. couperi*) is one of the few snakes generally liked by land owners as they consume venomous snakes. Indigo snakes, racers, and whipsnakes typically do not constrict their prey, instead swallowing it alive or in some cases pinning the prey against a surface until it stops struggling. Other colubrines have more restrictive diets, such as the green snakes (*Opheodrys*) of

the United States which feed primarily on insects and the scarlet, long-nosed, and patch-nosed snakes (*Cemophora*, *Rhinocheilus*, and *Salvadora*, respectively) which prey upon squamates and their eggs. Black-headed snakes (*Tantilla*) are centipede specialists while the scorpion-eaters in the genus *Stenorrhina* are aptly named, feeding almost exclusively on scorpions and spiders.

Natricine snakes in the New World include the garter and ribbon snakes (*Thamnophis*), watersnakes (*Nerodia*), the mostly soft-bodied invertebrate feeding *Storeria*, and the highly specialized crayfish snakes (*Regina*). These are small to mid-sized snakes with the garter and ribbon snakes (*Thamnophis*) having the most varied diets. While they primarily feed on soft-bodied invertebrates, fish, and amphibians, some have been known to feed on rodents. Watersnakes (*Nerodia*) typically feed on fish and amphibians with some like the Brown Watersnake (*N. taxispilota*) showing an affinity for preying on catfish. Among the most specialized of New World natricines are the crayfish snakes, which feed almost exclusively on crustaceans. The Queen Snake (*R. septemvittata*) is even more specialized, feeding only on soft-bodied freshly molted crayfish.

Dipsadinae are a highly diverse group of New World colubrids. There is a large subgroup known as "goo-eaters" which feed primarily on soft-bodied prey like slugs, snails, and earthworms as well as amphibian eggs. Many of these are small residents of forest litter like the coffee snakes of Latin America (*Ninia*). Others like *Sibon*, *Sibynomorphus*, and *Dipsas* are elongate with blunt heads. They are able to pull terrestrial mollusks from their shells. Another blunt-headed and very elongate dipsadine, *Imantodes* will seek out and feed on diurnal lizards as they sleep at night. Rear-fanged night snakes (*Hypsiglena*) also feed on lizards. The large semiaquatic *Farancia* of the southern United States feed only on elongate aquatic vertebrates like giant salamanders (*Amphiuma* and *Siren*) and freshwater eels. Also included in this group are the hognose snakes (*Heterodon*) of the United States and Mexico.

These snakes specialize in eating toads and have specialized rear-fangs that allow them to deflate and then consume toads that have inflated their bodies with air defensively. The snakes in the genus *Helicops* are similar in diet and life history to other groups of watersnakes (Homalopsidae and Natricinae). False water cobras (*Thamnodynastes*) also live semiaquatic lifestyles and feed on fish, but are notable for sometimes using their tails to probe for fish in riparian vegetation. The mussuranas (e.g., *Clelia* and *Pseudoboa*) are rear-fanged, yet also powerful constrictors that feed on other squamates and rodents.

### Food and Feeding Habits of Lizards (Lacertilia)

By far the most speciose and diverse of the Squamata, the lizards (Lacertilia or Sauria), comprise over 6,700 species at the time of this writing. This section will briefly cover the diets and notable specializations in the over 40 recognized families of lizards. Unless otherwise noted, information adheres to that provided in Pianka and Vitt (2003).

**Blind Lizards (Dibamidae):** The blind lizards contain 24 species and are globally disjunct, with one species, *Anelytropsis papillosus*, endemic to dry areas of eastern Mexico and all others in the genus *Dibamus* found in forests of southern Asia. There is very little data on diet for these animals.

**Southern Padless Geckos (Carphodactylidae):** This family of geckos is endemic to Australia and contains 30 recognized species. All are nocturnal and largely feed on arthropods. The knob-tailed geckos in the genus *Nephrurus* are all arid-adapted terrestrial species that are notable for having relatively large heads compared to their body size and feed on a variety of insects, other lizards, and even very small mammals (Cogger 1994).

**Flap-Footed Lizards (Pygopodidae):** There are nearly 50 species of these limbless or nearly limbless lizards. They are found almost exclusively in Australia with two species ranging into New Guinea. They occupy a variety of habitat types, with most species observed burrowing in sandy soils, occupying rock crevices, in ant or

termite mounds, under logs, or in low vegetation (Cogger 1994). The majority of species feed on insects and spiders. However, the two species of *Lialis* specialize in feeding on scincid lizards and have a hinged maxillary similar to the Round Island Boa (*Casarea dussumieri*).

**Diplodactylidae:** This highly diverse family (over 150 species) is found throughout Australia, New Zealand, and New Caledonia. It includes the world's largest gecko species, *Rhacodactylus leachianus*, which can be over 300 mm in length. Along with other members of this genus, they occupy forests and consume insects, other lizards, and fruits. On the opposite end of the spectrum are the ant and termite-feeding *Rhynchoedura*, which may only reach 90–100 mm in total length. Overall, though, this family can be considered dietary generalists that feed mostly on arthropods.

**Eyelid Geckos (Eublepharidae):** The eyelid geckos are found in North and Central America, Africa, Europe, and Asia and occupy a variety of habitats. They are mostly insectivorous and although many species are staples in private and zoological reptile collections around the world (e.g., the Leopard Gecko, *Eublepharis macularius* and Fat-tailed Gecko, *Hemiteconyx caudicinctus*), there is surprisingly little data on wild diets for many species. They are nocturnal with most being terrestrial in habit; however, the Malaysian cat geckos (*Aeluroscalabotes*) are often found in low vegetation (Seufer et al. 2005).

**Sphaerodactylidae:** This extremely diverse family of geckos contains over 200 species in nine genera. They are found in North and South America, the Caribbean, southern Europe, northern Africa, the Middle East, and Central Asia. They occupy highly diverse habitats from rainforests to dry deserts. In the New World, they include some of the world's smallest amniotes, with the West Indian *Sphaerodactylus ariasae* reaching a maximum total length of 30 mm. New World species of sphaerodactylids tend to be diurnal leaf litter and low vegetation dwellers and owing to their overall diminutive sizes, feed on equally tiny prey like ants, termites,

and springtails. In the Old World, they are represented in Europe by *Euleptes europaea*, a small (60–80 mm) insectivore, and elsewhere by *Pristurus*, *Saurodactylus*, and the fish-scaled *Teratoscincus*. Members of nocturnal *Teratoscincus* are mostly sit and wait predators that feed on arthropods.

**Leaf-Toed Geckos (Phyllodactylidae):** This large diverse family is distributed mostly through Central and South America north to the southwestern United States and Caribbean with additional members found in southern Europe, Africa, and the Middle East. They are found in a variety of habitats with many species occupying rocky areas in desert regions. They are generalist feeders of arthropods.

**True Geckos (Gekkonidae):** The true geckos are the most diverse of the gecko families and are among the most speciose of all lizard families with over 1,200 recognized species. They are primarily Old World in origin, although several species in the genera *Hemidactylus*, *Gekko*, *Gehyra*, and *Lepidodactylus* have spread beyond their historical ranges through accidental human introductions and can now be found almost globally. This family occupies nearly every nonpolar habitat type from rainforests with many being quite successful in developed urban regions. Overall, they are arthropod feeders, although many species, especially the Madagascan Day Geckos in the genus *Phelsuma*, are known to include a notable proportion of fruits and nectars in their diets. Some larger species, like the 300+ mm *Gekko gecko*, will also feed on other vertebrates.

**Night Lizards (Xantusiidae):** The Night Lizards are found in southwestern North America, Central America, and Cuba. Although commonly called “night lizards,” many xantusiids are primarily diurnal. Many live in rocky habitats, although species of *Lepidophyma* are typically found in tropical forests. All species feed on a variety of arthropods.

**Plated Lizards (Gerrhosauridae):** This family of lizards are found only in Africa and Madagascar. They are diurnal and largely terrestrial. They primarily feed on a wide variety of

arthropods, although some have been observed to eat fruit.

**Girdled Lizards (Cordylidae):** The 68 species of cordylid lizards are found only in Africa. They tend to be found in overall dry habitats. Most species are sit and wait predators on arthropods, although some species of Flat Lizards (genus *Platysaurus*, so-called due to their dorsoventrally flattened bodies) also consume flowers, leaves, and seeds.

**Skinks (Scincidae):** Probably the most globally and species diverse family of lizards, the Scincidae contains over 1,650 species that can be found in nearly every nonpolar region of the globe. They are highly diverse in size and morphology with many limbless or nearly limbless forms included in the family (e.g., *Brachymeles* of the Phillipines and the Australian *Lerista*). Given this diversity, it can be easily inferred that diets are equally diverse. While most species feed on a variety of arthropods, some, like the 80+ cm Prehensile-tailed Skink (*Corucia zebrata*) of the Solomon Islands are largely herbivorous, while many more include a variety of vegetation, arthropods, and other vertebrates in their diets.

**Tegus and Whiptails (Teiidae):** The New World Teiidae contains over 150 species that occupy a variety of habitats and niches. These are mostly diurnal, actively foraging predators that operate at high body temperatures. The aptly named racerunners and whiptails in the genera *Aspidoscelis* and *Cnemidophorus* live in mostly desert and semiarid habitats that forage widely for insects, spiders, and other arthropods, typically at the warmest part of the day (Jones and Lovich 2009). The overall larger species of *Ameiva* occur in open, forested, and edge habitats throughout much of Central and South America, and the Caribbean. They feed on a variety of invertebrates, small vertebrates, and fruits. The South American *Dracaena* and *Crocodylurus* are semiaquatic. While *Crocodylurus* appear to be dietary generalists feeding on whatever small vertebrates and invertebrates they can capture, *Dracaena* primarily feeds on hard-shelled mollusks, even having

large, rounded teeth specialized for crushing their shells. Some members of the genera *Tupinambis* and *Salvator* can get quite large (over 1 m in length). All are dietary generalists feeding on invertebrates, vertebrates, mollusks, carrion, and eggs. *Tupinambis teguixin* have been observed raiding turtle nests.

**Spectacled Lizards (Gymnophthalmidae):** Found strictly in the New World, this family contains nearly 250 species and includes some of the world's smallest lizards. They range in habit from terrestrial to semiaquatic, with some being somewhat arboreal as well. Interestingly, gymnophthalmids can occur in relatively high species diversities in relatively small areas. All feed on small invertebrates.

**Florida Worm Lizard (Rhineuridae):** This monotypic family includes only the limbless and blind Florida Worm Lizard (*Rhineura floridana*) which is found in areas with deep sandy or loamy soils suitable for burrowing. This completely fossorial lizards feed on earthworms, spiders, and termites (Gibbons et al. 2009).

**Two-Legged Worm Lizards (Bipedidae):** The three species of *Bipes* are found only in Baja California and mainland Mexico. As suggested by their common and generic names, *Bipes* have only two front limbs. They are considered generalist invertebrate predators, although in one dietary study the most common prey detected were ants and termites (Kearney 2003).

**Mediterranean Amphisbaenians (Blanidae):** This small family (seven species in the genus *Blanus*) of limbless reptiles is found only in the Mediterranean region of Europe and Africa. Research shows that at least *B. cinereus* feeds largely on insect larvae and ants (López et al. 1991).

**Cuban Keel-Headed Worm Lizards (Cadeidae):** Both species in this family are in the genus *Cadea* and endemic to Cuba. There is scant information on diet for these limbless reptiles but based on other worm lizards can be inferred to be primarily invertebrates.

**Short-Headed Worm Lizards (Trogonophiidae):** The six species of limbless Trogonophiidae are sand burrowing specialists

found in northern Africa and the Middle East. A dietary study of *Trogonophis wiegmanni* (Martin et al. 2013) found insect larvae, beetles, ants, isopods, and snails.

**Worm Lizards (Amphisbaenidae):** This is the largest group of the so-called worm lizards or amphisbaenians with 175 species. They can be found in South America, the Caribbean, and sub-Saharan Africa. Some species, like the South American *Amphisbaena alba*, can get quite large, measuring over 700 mm. However, despite this, like most other worm lizards, they feed primarily on very small prey like ants and termites. Also, as with other worm lizards, they are blind and limbless.

**Wall Lizards (Lacertidae):** Found in Europe, Africa, and through a large part of Asia, the Lacertidae contains over 300 species. Most are rock dwellers, although some like *Holaspis* and *Takydromus* spend time in vegetation and trees. Overall this family contains dietary generalists that feed largely on invertebrates. For example, *Gallotia* are endemic to the Canary Islands and omnivorous, feeding on a variety of animals and plants. However, specialists do occur within this family such as *Nucras tessellata* from the Kalahari of southern Africa, which feeds primarily on scorpions and may forage for long distances to find them during the day. Ants may be the primary dietary component for some species of *Acanthodactylus*.

**Knob-Scaled Lizards (Xenosauridae):** There are 12 species of *Xenosaurus*. All are found in crevices in rocks, trees, or even buildings. These lizards are found only in Mexico and Guatemala. Dietary studies have found that insects (mostly beetles and orthopterans) comprise the majority of the diet, but evidence of mammalian prey and vegetation was also observed (Lemos-Espinal et al. 2003).

**Gila Monsters and Beaded Lizards (Helodermatidae):** This group of venomous lizards are found in the southwestern United States, Mexico, and Guatemala. They are quite large with some specimens of *Heloderma horridum* reaching nearly a meter long. The Gila Monster (*H. suspectum*) occupies arid

deserts while the beaded lizards occupy mostly dry forests. All *Heloderma* primarily prey upon nests of birds and rodents, although some include a large portion of reptile eggs in their diets as well.

**California Legless Lizards (Anniellidae):**

These legless lizards are found in coastal California and western Baja, California. They are found in loose soils and likely feed mainly on termites.

**Alligator and Glass Lizards (Anguidae):**

There are nearly 80 species of this wide-ranging family of lizards. They can be found in the Americas, the Caribbean, Asia, Europe, and northern Africa. Although mostly terrestrial, the Mexican, and Guatemalan alligator lizards in the genus *Abronia* are highly arboreal. All have powerful jaws and a number have reduced limbs or are totally limbless (i.e., *Ophisaurus*). Most species feed on arthropods and other invertebrates, although the European limbless Slow Worms (*Anguis*) seem to feed mainly on slugs and snails.

**Asian Crocodile Lizards (Shinisauridae):**

*Shinisaurus crocodilurus* is found in southern China and northern Vietnam. This species is diurnal and semiaquatic, feeding on a wide variety of prey including earthworms, insects, tadpoles, frogs, and fish which they may sometimes forage for underwater.

**Bornean Earless Monitors (Lanthanotidae):**

Found only in Borneo, *Lanthanotus borneensis* reaches up to 43 cm in total length and is poorly known. They appear to burrow in mud and have aquatic tendencies. Very little is known about their wild diet, although earthworms appear to be a component.

**Monitor Lizards (Varanidae):** The monitor lizards are native to Africa, Asia, New Guinea, and Australia. They include the world's largest lizard, the Komodo Dragon (*Varanus komodoensis*) which can reach 3 m in total length and weigh over 100 kg. Contrastingly, the smallest monitor lizard, the Short-tailed Monitor (*V. breviceauda*) only reaches a length of 20 cm and less than 20 g. Monitors are carnivorous, feeding on anything from insects and other arthropods to large mammals. Most species are active predators, with many foraging for long distances and serving

as top predators in their environments. The teeth of many larger varanids, like Komodo Dragons, are curved and serrated, allowing them to inflict severe wounds on larger prey. Some of these larger species can consume meals  $\geq 50\%$  of their own body mass. Although largely carnivorous, at least one species, *V. olivaceus*, includes fruit in its diet.

**True Chameleons (Chameleontidae):**

The chameleons are among the most recognizable lizards with their color-changing abilities, laterally flattened bodies, individually mobile eyes, and zygodactylous limbs. Perhaps their most unique adaptation when it comes to feeding is the exceedingly long projectile tongue found in all species, which in some can be longer than the length of the body. These tongues can be fired at incredible speed at prey. The end of the tongue is sticky and wraps around a prey item before the tongue is retracted back into the mouth. Some species possess glands at the edges of the mouth that produce smelly secretions that could potentially act as "bait" for insect prey. All species are carnivorous, feeding primarily on insects of varying sizes, though some larger species will include other lizards, rodents, and small birds.

**Agamidae:** The agamids are small to large diurnal lizards found across much of the Old World and Australia. The family includes nearly 500 species. They range in size from the small "flying" dragons in the genus *Draco* of Southeast Asia to the large bearded and frilled dragons of Australia (*Pogona* and *Chlamydosaurus*, respectively). They also occupy highly varied habitats. While most species are carnivorous, there are mostly or strictly herbivorous forms. An example is the semiaquatic sailfin dragons in the genus *Hydrosaurus*. The bearded dragons, including the commonly captive maintained *Pogona vitticeps*, are dietary generalists, feeding on a variety of animal prey and vegetation. The spiny-tailed *Uromastyx* of northern Africa and the Middle East are primarily herbivorous but will occasionally consume insects. An extreme myrmecophagous (ant eating) species is the Australian Thorny Devil or Moloch (*Moloch*

*horridus*) and a single animal may eat over 2,000 ants in one meal.

**Tropiduridae:** This relatively large family of lizards (137 species) is distributed in South America, the Galapagos Islands, and Trinidad. They feed mostly on invertebrates, with a fair number specializing in ants. The species *Uranoscodon superciliosus* is known to feed on both living and dead invertebrates that wash up along the edges of waterways.

**Iguanas (Iguanidae):** Although mostly found in the Americas from the southwestern United States into central South America and the Caribbean, there are iguanas found on the Pacific islands of the Galapagos and Fiji. They occupy a variety of habitats from deserts (i.e., *Dispsosaurus dorsalis*) to dense rainforests (i.e., *Iguana iguana*). These lizards are generally rather large with some species nearing 2 m in length (i.e., *I. iguana*) and largely herbivorous, although members of *Ctenosaura*, *Dispsosaurus*, and *Cyclura* are more omnivorous in habit, eating vegetation, invertebrates, small mammals, carrion, and even the feces of other animals. Perhaps the most specialized in the group is the Galapagos Marine Iguana (*Amblyrhynchus cristatus*) which dives from coastal rocks into the ocean to scrape algae from submerged rocks.

**Curly-Tailed Lizards (Leiocephalidae):** The family Leiocephalidae includes 31 species that are found only on islands in the Caribbean. These small- to medium-sized diurnal lizards (up to 140 mm) are terrestrial, live in mostly xeric habitats and have varied diets. They consume insects, other lizards, and a variety of plant matter, including fruits and flowers.

**Collared and Leopard Lizards (Crotaphytidae):** These relatively large-bodied diurnal lizards are only found in the United States and Mexico. There are two genera, *Crotaphytus* and *Gambelia*. They may adopt a fast-moving bipedal gait when chasing down prey, which includes large arthropods and smaller vertebrates, particularly other lizards. The Leopard Lizards in the genus *Gambelia* are particularly well-known as lizard predators, and all species in the family may be cannibalistic (Jones and Lovich 2009).

**Horned and Spiny Lizards (Phrynosomatidae):** This family contains 159 recognized species and ranges from southern Canada to Panama. Phrynosomatids are relatively small to medium lizards reaching maximum lengths 150 mm. They are diurnal and occupy a wide range of habitat types from arid deserts to tropical forests. Most species are insectivorous and employ ambush foraging, although some species are known to eat some plant matter as well. The Horned Lizards in the genus *Phrynosoma* are ant specialists.

**Monkey Anoles (Polychrotidae):** This family, includes eight species and is found through a large portion of Central and South America. They are diurnal and feed on arthropods that are relatively large compared to their body size but also consume some fruit, flowers, seeds, and leaves. They very slowly advance on arthropod prey once spotted (Savage 2002).

**Wood Lizards (Hoploceridae):** This family of small- to medium-sized lizards is found in Panama and South America. While *Hoplocercus* tend to occupy dry forest or grasslands, *Enyalioides* and *Morunasaurus* are found in rainforests. There is little information on the natural history of these lizards; however, they are presumed insectivores.

**Madagascan Iguanas (Opluridae):** These mid-sized lizards are endemic to Madagascar and nearby islands. All are diurnal and prefer hot, dry habitats. They are omnivorous.

**Leiosauridae:** There are 33 species in this strictly South American family. All are insectivores.

**Lava Lizards (Liolaemidae):** There are over 300 species in this South American family. They can be found in every habitat type South America has to offer. Most are omnivores, but species of *Phymaturus* are herbivores.

**Helmeted Iguanas and Basilisks (Corytophanidae):** The Corytophanidae are generally medium to larger lizards found from Mexico to northern Ecuador. The helmeted iguanas *Corytophanes* and *Laemactus* are arboreal forest-dwellers while the basilisks (*Basiliscus*) are typically found along forested riparian zones. The

basilisks are omnivorous, feeding on arthropods, smaller terrestrial vertebrates (including lizards, snakes, small mammals, and birds), freshwater shrimp, fish, and fruits and flowers of streamside plants. *Corytophanes* are sit and wait predators that primarily feed on large-bodied insects including large orthopterans, lepidopteran larvae, and smaller lizards (Savage 2002). *Laemancus* are largely insectivorous but will also eat snails, frogs, and smaller lizards (Campbell 1998).

**Anoles (Dactyloidae):** The anoles are found strictly in the Americas and the islands of the Caribbean. Anoles range in size from 33 to nearly 200 mm in total length and are dietary generalists. While largely insectivorous, frugivory has been observed in several taxa, while some of the larger forms will feed on other vertebrates and terrestrial mollusks (Losos 2009).

## Conclusion

Squamates are the most diverse extant group of reptiles. As such, across their phylogeny exists a wide range of dietary preferences and adaptations. From projectile tongues to catch insect prey with immense accuracy to loosely constructed skulls that allow many snakes to consume prey larger than their own heads, the variation of adaptations to meet various dietary challenges within the Squamata is impressive.

### What Is Communication?

In zoology, communication is known as a channel established between species, individuals, or groups, allowing taxa to evolve and coevolve (Hauser 1996). For such bonds to be created, an individual (sender) sends a message encoded with information that must be accepted and understood by another individual (receiver). Therefore, communication itself relies on the necessity of both the reception and understanding of the message – otherwise communication will not be accomplished (Bradbury and Vehrencamp 2011). The high diversity in animal communication systems arises from several factors such as (i) physiological mechanisms, constrained by physical properties such as ambient medium and habitat mobility; (ii) phylogenetic proximity, i.e., animals that are evolutionarily closer are usually more similar; (iii) and the economics of communications, i.e., the energetic and anatomical costs or both producer and receiver in the communication episode (Bradbury and Vehrencamp 2011; Hauser 1996). Although such kinds of messages are diverse in terms of their types, the

information provided by the sender can be traditionally classified in two main categories: cues and signals.

Cues are known as the stimuli received and processed by the receiver, even though the sender generated the signal inadvertently or for purposes other than communication (Hauser 1996). For instance, when a prey unintentionally vibrates a spider's web, it sends information that is decoded by the receiver as evidence of its presence. Another typical example is when a predator is looking for its prey using its own olfactory system (as dogs or even sharks). The cue in this case is the prey's smell. All metazoans monitor ambient cues by their extremely specialized sensory organs that have evolved to track cues with accuracy and speed (Bradbury and Vehrencamp 2011). Such detection is usually achieved through the combination of several sensorial specializations to monitor olfactory, visual, auditory, and other cues (Bradbury and Vehrencamp 2011; Hauser 1996).

Unlike unintentional cues, signals are intentionally produced by the sender to provide information to another individual (Bradbury and Vehrencamp 2011; Hauser 1996). Such kind of communication varies in terms of its function, such as to find a female for reproduction or to deter a predator. For example, during breeding season, a frog can share a pond with dozens of conspecifics, competing through their calls to attract females (Vitt and Caldwell 2014). As signals are mandatorily produced by the sender and monitored by the receiver, one might assume that there is intrinsic coevolution between both parties that has been favored over the evolutionary time (Bradbury and Vehrencamp 2011).

Animals can use plenty of sensory systems to communicate through signals, and one might summarize the main signals as tactile/seismic, chemical/olfactory, visual, and acoustic (Hauser 1996). However, the channel chosen to transfer messages depends on many factors, such as the morphofunctional structure of the organisms involved, as well as the characteristics of the environment (Dugatkin 2019). Additionally, animals may use signals that are multimodal, combining two or more modalities of the aforementioned categories. For instance, while many birds usually

combine both visual and acoustic components, some insects might combine visual and chemical stimuli for communication (Bradbury and Vehrencamp 2011).

Tactile communication – as touches and bites – are employed in short-range interactions, when the sender and the receiver are physically close (Hauser 1996). This mean of communication is widespread among arthropods and vertebrates and most commonly targets nearby individuals (Bradbury and Vehrencamp 2011). For instance, the function of a touch during mating season can discern a receptive from a non-receptive individual for copulation. This type of communication is common in large-sized mammals such as elephants, whose fights among rivals usually involve physical clashes (Poole and Granli 2004). Seismic communication occurs when the signal is transmitted through vibrations of the substrate in which both sender and receiver are on, whether through the ground, water, or any other surface (Hill 2008). This way of communicating is known to be one of the most ancestral modes of communication among animals. For example, male crocodilians produce subaudible vibrations that make the water “splash” in order to attract females (Vergne et al. 2009).

Chemical communication is based on chemical molecules, with the receiver accepting the message contained in one or more molecules, which can generate reactions of fear/stress (e.g., when from rivals or predators) or motivation/excitement (e.g., when produced by potential mates) (Bradbury and Vehrencamp 2011). Pheromones impact the behavior of the receiving individuals from the same species, such as in court rituals, or in differentiating an intruder from its neighbor (Wyatt 2003). In addition, allelochemicals – another way of chemical communication – affect the behavior of an individual of a different species (Sbarbati and Osculati 2006).

Visual communication uses colors, patterns, and movements as a mean of sending information (Bradbury and Vehrencamp 2011). It is very widespread among metazoans and consequently derives from the evolution of sensorial mechanisms for understanding and processing visual elements. This type of language can be easily

detected in iguanian lizards, in which males can bob heads and make push-ups to attract females and to defend territories (Vitt and Caldwell 2014). This kind of communication is also common within birds, where males can make use of several body ornaments and exhibit gifts to attract females, as in courtship dances of birds-of-paradise (Bradbury and Vehrencamp 2011).

## Acoustic Communication

For many animals, the main mode of communication relies on sound emission and acoustic communication. Living beings have evolved to capture and generate information by sound waves for many different reasons (Hauser 1996). Whether to be located in the environment, as bats and cetaceans do through echolocation (Berta et al. 2015), or for predatory, reproductive, or social interests, such a mode of communication is very widespread among living metazoans (Suthers et al. 2016). Among terrestrial vertebrates, historically much is known about acoustic communication in birds, mammals, and anurans, but recent evidence has pointed out that non-avian reptiles also play an important role in the understanding of the evolution of vocalization in amniotes (Russel and Bauer 2020).

In general, the acoustic signals produced by aquatic and terrestrial vertebrates can be classified into two main categories: vocal and nonvocal sound emissions (Suthers et al. 2016). Nonvocal emissions may involve a variety of sound-generating ways, such as integumentary mechanisms, hitting a given substrate, or sounds generated by different body parts. In contrast, in a broad sense, vocalization can be defined as the sound produced by air passing through the upper respiratory tract, not necessarily but usually involving the vocal cords/folds (Ladich and Winkler 2017).

These tubelike structures are present in vertebrates, but are more widespread in Tetrapoda, where the system is composed of lungs connected to the bronchus and trachea, connected to the outside by the oral cavity and nasal cavity (Bradbury and Vehrencamp 2011). Even though most terrestrial vertebrates share this basic design,

their vocal sound production is extremely varied. While frogs use a buccal pumping for sound production, lizards and snakes use their ribs and costal muscles to allow the expansion of the thoracic cavity (Colafrancesco and Gridi-Papp 2016). However, many extant non-avian reptiles do not vocalize, with a few exceptions for some turtles and tortoises, most gecko lizards, and most crocodilians (Russel and Bauer 2020; Vergne et al. 2009). Birds, on the other hand, use an extremely evolved anatomical mechanism that involves the air sacs and the presence of specialized cartilages and muscles called syrinx (Bradbury and Vehrencamp 2011). The larynx of mammals may present a variety of sizes and shapes, enabling the production of sounds from infrasounds in elephants to ultrasounds in toothed whales (Ladich & Wincler, Ladich and Winkler 2017). In this context, echolocation is a specific way of using vocalization, commonly used to map an environment or to locate a prey, in which the information is sent and accepted by the same individual. Present in bats and cetaceans (Bradbury and Vehrencamp 2011), this mechanism is defined by the emission of short duration sound waves, which echo when hitting an object or prey and return to the emitter (Berta et al. 2015). In cetaceans, such vocalizations are allowed by the presence of a melon (a mass of adipose tissue on top of the skull) and cranial and facial asymmetry (Berta et al. 2015).

Even though several fundamental questions regarding the origins and diversification of acoustic communication in tetrapods still remain (Suthers et al. 2016), recent studies have revealed intriguing patterns comparing aquatic and terrestrial vertebrates (e.g., Ladich and Wincler 2017). Additionally, other recent contributions reveal the phylogenetic nature of acoustic communication as being strongly conserved in tetrapods and that it is mostly related to the evolution of nocturnal habits (Chen and Wiens 2020). In addition, once the majority of main groups of vertebrates that communicate through acoustic signals (birds, frogs, mammals, crocodilians, and gekkotan lizards) are ancestrally nocturnal, the origins of acoustic communication seem to be intimately associated with nocturnal activity (Rohtla Jr. et al. 2019;

Chen and Wiens 2020). That makes sense when considering that during nighttime, visual signs such as color, body movements, and tactile signals are negatively affected. Furthermore, it was demonstrated that acoustic communication arose independently across major tetrapod groups, despite ancient origins in many of them (Chen and Wiens 2020). Being present in several groups and having arisen many times, it is not a surprise that acoustic communication would also be expressed in different manners and complexities, as previously presented.

In view of the extensive variation of sound emission among well-studied species and scarcity of information for many groups, the ethological knowledge around animal's communication remains a promising field for scientific research with deep gaps to be filled.

## Acoustic Communication in Squamata

Among non-avian reptiles, acoustic communication is used with several purposes and in a variety of contexts such as interaction between mother and offspring (e.g., crocodilians), for territorial interactions (e.g., geckos), and for mating (e.g., tortoises, Gans and Maderson 1973).

With more than 11,000 species, Squamata are considerably more diverse than amphibians and mammals (Uetz et al. 2021). This taxon congregates "lizards," snakes, and amphisbaenians, which, despite their well-established common ancestry, still have uncertain evolutionary relationships between many groups. This group exhibits several ways of intraspecific and interspecific acoustic communication that vary from integumentary mechanisms, sounds generated by different body parts, and true vocalizations (Gans and Maderson 1973). The acoustic communication currently known for snakes includes integumentary sound production such as tail vibration and scale abrasion, as well as sounds derived of air expulsion by the cloaca, and oral sounds as hissing and growling (Russel and Bauer 2020; Young 2003). Integumentary mechanisms involve intentional friction between parts of the body, with tail vibration being the most typical example of

this kind of communication (Gans and Maderson 1973). This type of percussion is used by rattle-snakes as a way to ward off possible predators and occurs through the sound produced by the rings of a snake's rattle when rubbed (Young 2003). Scale abrasion consists of another integumentary mode of sound production in which the sound is produced when a snake coils itself in a c-shaped formation, also used as a defense mechanism (Gans and Maderson 1973). Cloacal pops – also known in a few geckos – consist of a sound produced by synchronized muscular contraction that results in passing air through the cloaca, added with fecal elimination, the latter also being employed as a defensive strategy (Young 2003). Snakes are also able to produce sounds by forcible oral expulsion of air through the glottis, commonly named as hissing (Gans and Maderson 1973; Young 2003). These sounds are used to intimidate and/or to drive intruders off, occurring in some species of many families such as Viperidae, Colubridae, Boidae, and Elapidae (Russel and Bauer 2020). However, although sound emissions in snakes are not usually interpreted as acoustic signals for intraspecific communication, some species emit more complex sounds involving anatomical specializations to phonation (Young 2003). For instance, the King Cobra (*Ophiophagus hannah*) produces growls involving the presence of tracheal diverticula that works as a resonance chamber and filter (Young 1992), while the Pine Snake (*Pituophis melanoleucus*) possesses a vocal cord-like laryngeal septum able to produce harmonics, and the glottal control allows emission of two kinds of oral exhalations, hisses which are acoustically simpler and bellows which include frequency and amplitude modulation (Young et al. 1995).

While there seem to be no sound emission records for amphisbaenians – even though these animals have functional inner ears (Wever and Gans 1973) – sound emissions are widespread among other “lizards” (Russel and Bauer 2020). Undoubtedly, the acoustic communication in Squamata is more conspicuous and better understood among geckos (Rohtla Jr. et al. 2019). However, oral sounds can be found in several non-gekkotan lizard families, mainly in the form of hisses and squeaks (Gans and Maderson 1973;

Russel and Bauer 2020). Although in general such sound emissions have a relatively simpler structure and are usually exhibited in anti-predatory contexts as distress calls (e.g., *Tropidurus catalanensis*; Fernandes and Passos 2021), some species can show considerable variation in their hisses, indicating potential intraspecific vocal communication (e.g., *Liolaemus chiliensis*, Labra et al. 2016). On the other hand, most gekkotan lineages produce true vocalizations, including a wide array of hisses, squeaks, and chirps as part of their vocal repertoire (Rohtla Jr. et al. 2019). The complex acoustic structure of geckos' calls with tonal and harmonic qualities coupled with a high hearing capability is made possible due to derived characteristics of the laryngotrachea and inner ear (Russel and Bauer 2020, but see next section). Being issued by males, females, and juveniles, gecko calls can be used in a variety of behavioral contexts (Rohtla Jr. et al. 2019): when escape is needed (as an antipredatory mechanism), during agonistic interactions among rivals (e.g., defending territories or competing for resources), and in the course of mating behavior (courtship or copulation). The extension of variation in the vocalizations of geckos is almost as extensive as diversity of clade Gekkota, with some species producing vocalizations that can be heard over a hundred of meters (e.g., *Ptenopus garrulus*, Hibbitts et al. 2007) and other species with even the presence of interpopulational dialects (e.g., *Gekko gecko*, Yu et al. 2011).

### Anatomical Structures Associated with Vocalization in Squamata

The vocal apparatus of squamates is composed of the basic design of tetrapods: it consists of a tube that passes and modulates air as it inhales and expels air from the paired lungs (Russel and Bauer 2020). Air inhalation and exhalation are acquired through a very derived mechanism acquired by costal muscles and ribs' expansion to aspirate air (Bradbury and Vehrencamp 2011). As with other terrestrial vertebrates, the glottis represents a valve that allows vocal vibrations at the top of the trachea, with the vocal cords being

located at the glottal lips (Bradbury and Vehrencamp 2011; Russel and Bauer 2020).

Even though the basic squamate design is clear, the functional relationship with form and function has been underrepresented for their lineages. For example, vocal cord-like structures are only described for a few “lizard” species (see Russell and Bauer 2020 for a comprehensive review) and a unique snake species (*Pituophis melanoleucus*, Young et al. 1995). However, only gekkonids hold true vocal cords that are rich in elastin, with laryngeal size and tracheal dilatation being associated with acoustic properties of their vocalizations (Rohtla Jr. et al. 2019). The true vocal cords are located at the modified glottis, modulating the air as it passes by, therefore producing sounds typically categorized as vocalizations (Russel and Bauer 2020). Although the vocal cords are the main structure that participates in the generation of this type of acoustic communication, other structures associated are equally important in sound production, as cartilages and muscles contained in the laryngotracheal region (Russell et al. 2000). For instance, despite the simplified laryngotracheal region of snakes, intrinsic musculature of the larynx might modify the glottal opening shape providing modulation during hissing of a few snake species (Russel and Bauer 2020; Young 2003). Also, the emission of call with harmonics of a few non-gekkotan lizards suggests the existence of a modified laryngotracheal anatomy; other non-gekkotan lizards use other body parts for modulating the frequency of hisses, such as nasal passageways as resonators and gular inflation (Russel and Bauer 2020; Young 2003). Finally, the shape and size of arytenoid cartilages might play an important role in differentiating vocalizing and nonvocalizing lacertids (see Russel and Bauer 2020 and references therein).

The laryngotracheal region, supported at the mouth’s floor by the hyoid apparatus through attached muscles and ligaments, comprises, as the name suggests, the larynx and the trachea (Moore et al. 1991). The trachea is a tubelike-shaped respiratory organ which delivers air from the lungs to the larynx and vice versa (Russel and Bauer 2020). It is mainly composed of cartilaginous tissue organized as several continuous and

uniform horizontal rings one on top of the other through the whole tracheal length (Russell et al. 2000). Even though this represents the basic configuration of the tracheal rings, some variation is common to occur. For instance, *Afroedura pondolia* and *Chondrodactylus bibronii* (= *Pachydactylus bibronii* in Russell et al. 2000) can present ring bifurcations and ring fusions in their trachea (Russell et al. 2000). However, some species diverge vastly from this common variation. *Ptenopus garrulus*, for example, presents a longitudinal invagination produced by the folding of the trachea on itself, with the left side overlapping the right side, and this invagination creates a sequence of incomplete tracheal rings (Rittenhouse et al. 1998), whereas in *Chondrodactylus angulifer*, its incomplete tracheal rings are even more slip apart, forming a pronounced mid-dorsal gap (Russell et al. 2000). Such a variation still remains to be explored in terms of its morphofunctional aspect, but there seems to be a relation of the tracheal width with call frequency parameters in several gekkotans (Rohtla Jr. et al. 2019). Sexual dimorphism in both trachea and larynx might also be associated with changes in vocalization mechanisms in this lineage (Moore et al. 1991).

The larynx consists of two cartilages – the cricoid and arytenoid cartilages – and two pairs of intrinsic muscles, the *musculus constrictor laryngis* and *musculus dilator laryngis* (Russell et al. 2000). The cricoid cartilage is the main structural piece of the larynx, to which all intrinsic muscles are associated with (Russel and Bauer 2020). The quality of sound generated depends on their form, dimension, and tension placed, as well as additional factors that include the presence of a resonating chamber, air pressure, and size of glottal opening during phonation (Russell et al. 2000).

The anatomy of the larynx is variable between taxa, mostly regarding their general shape and size (Rohtla Jr. et al. 2019). For instance, while *Gekko gecko* bears a ring-shaped cricoid cartilage (Moore et al. 1991), *Ptenopus garrulus* presents a diamond-shaped cricoid due to its large lateral processes (Rittenhouse et al. 1998). The arytenoid cartilages, on the other hand, represent small paired pyramidal pieces

connected to the anterior portion of the cricoid cartilage (Russell et al. 2000). This cartilage also greatly vary among lizards and might be associated with different air modulation in vocalizing species. In snakes, there seems to be no relation between the laryngeal morphology and either phylogeny or habitat preference – therefore, the ophidian larynx seems to be evolutionarily very plastic, and its plasticity is most likely associated with more complex vocalizations, as in *Pituophis melanoleucus* and *Ophiophagus hannah* (Russel and Bauer 2020).

The *M. constrictor laryngis* – responsible for compressing the larynx – has its point of origin located posteriorly to the basihyoid process, inserting itself on the midline of the dorsal face of the larynx (Russell et al. 2000; Russel and Bauer 2020). The *musculus dilator laryngis*, responsible for opening the glottis, has its point of origin close to the glottal tube and inserts itself into the arytenoid cartilages (Russell et al. 2000; Russel and Bauer 2020). Both muscles also exhibit several interspecific variations in vocalizing lizards and are directly associated with different morphofunctional consequences for vocal chords. For instance, while the muscle arrangements of *Gekko gecko* performs the dorsolateral rotation of the arytenoids, consequently increasing the tension above the vocal cords, in *Ptenopus garrulus* it elevates dorsally the vocal cords, juxtapositioning them (Rittenhouse et al. 1998). Therefore, sites of origin and insertion of laryngeal muscles as well as fiber orientation are directly involved in different vocalizations and deserve to be taken into account in any morphofunctional perspective of phonation in Squamata (Russel and Bauer 2020).

Finally, although even less studied and sometimes forgotten, the tracheal diverticula represent chambers of thin and delicate connective tissue externally connected to the trachea (Young 1992). These specialized structures are associated with more complex vocalizations and have been described only in a few genera of colubroidea snakes (Young 1991), and it is so far known that the size and shape might act as resonating chambers that determine the frequencies that are

emitted (Young 1991). The role of the diverticulum in non-gekkotan lizards, however, still remains as speculative (Russel and Bauer 2020).

## Squamate Cognition

Enrique Font

Instituto Cavanilles de Biodiversidad y Biología Evolutiva, University of Valencia, Paterna (Valencia), Spain

## Introduction

Reptilian cognition is paradoxical. Judging by their phylogenetic position, brain size and organization, and the complexity and sophistication of their behavior, one would expect the cognitive achievements of reptiles to be on a par with those of other vertebrates. However, there is a widespread (mis)perception that reptiles, and squamates in particular, are the cognitive morons of the vertebrate radiation. In fact, to some the expression “squamate cognition” could almost be considered oxymoronic, so entrenched is the idea that lizards and snakes are essentially instinct machines, inflexible and lacking even the most basic intellectual abilities. But the myth of squamates as stupid, lumbering brutes is out of kilter with the conclusions from a small but growing literature that shows that squamates have flexible, sophisticated behavior and display a startling array of cognitive skills. This entry will provide a brief review of the current state of knowledge regarding squamate cognition.

With more than 10,000 species in over 70 families, Squamata is the largest order of living reptiles and an extremely diverse group in terms of morphology, development, ecology, reproduction, and sociality. Squamata is considered a monophyletic clade, but there is considerable debate about the phylogenetic relationships among the different families and larger groups included in it. As currently conceived, Squamata comprises lizards, snakes, and the lesser known amphisbaenians (worm lizards). Despite its generalized use, the term “lizard” does not designate a valid, accepted group (i.e., a clade). Snakes and amphisbaenians are just specialized lizards, and therefore there is no monophyletic clade that includes lizards and excludes snakes and amphisbaenians. The lizard-like tuataras from New Zealand are the sister group of squamates, and together, squamates and tuataras make up the Lepidosauria, the sister group of Archelosauria (turtles, crocodiles, and birds).

Reptiles have generally been given scientific short shrift in favor of more amenable subjects like birds, mammals, or even fish. As a result, their cognitive abilities have rarely been tested. Research on reptile cognition has traditionally emphasized work with turtles, with squamates receiving far less attention. This is in part due to the mistaken belief that turtles are “living fossils” that somehow resemble the ancestral condition at the reptile-mammal transition. However, in the last decades, there has been a steady flow of studies probing different aspects of squamate cognition. This small but growing body of relevant research has shown that squamates are capable of problem-solving and of most major types of learning provided that the experimental design takes account of some peculiarities of their biology. The behavioral evidence also refutes the caricature of squamate behavior as being simple, clumsy, inflexible, and instinct-driven. Recent work has shown that squamates possess elaborate communication and social systems, parental care, and even play. They benefit from enrichment; form bonds with their caretakers, whom they recognize individually, and are affected by early social isolation much as birds and mammals do.

Although squamate cognition is a rapidly growing subject, the growth is uneven, with

some aspects of cognition, as well as some species groups, covered more deeply than others. Most of the available information concerns learning, while other aspects of cognition (e.g., categorization, concept formation, planning, episodic memory, problem-solving, tool use, metacognition) remain relatively unexplored in this group. Lizards are the leading taxon, with the largest number of studies. Studies of snake cognition are relatively few in comparison, while those dealing with amphisbaenians are virtually nonexistent. Australian skinks and spatial and social learning in particular have received a lot of attention, with several recent reviews.

## Cognition and the Squamate Brain

Recent interest in squamate cognition has not been accompanied by a corresponding interest in its underlying neural mechanisms. A notable exception is the recent focus on the role of the hippocampus in spatial cognition (e.g., Roth et al. 2019). Also, there seems to be a disconnect between cognitive/behavioral and brain studies, insofar as what little neuroscience research is currently done with lizards and snakes often relies on species that are not necessarily those for which cognitive/behavioral data are more abundant.

The extent to which absolute or relative brain size is a product or a driver of behavioral and cognitive complexity is a contentious issue. While there is some evidence that larger relative brain sizes are associated in living vertebrates with more complex cognition, work with invertebrates has shown that complex cognitive functions can be implemented with behavioral shortcuts requiring only the simplest neural circuits. Squamates and other reptiles are widely considered small-brained compared to birds and mammals. In fact, brain size has often been used to justify claims about the presumed intellectual backwardness of squamates, their small brains allegedly precluding flexible, intelligent behavior. However, while it is true that the brain of a lizard or a snake is, on average, smaller than the brain of a bird or a mammal of similar body weight, the difference has been grossly overestimated (Font et al. 2019).

Another misconception that has plagued research on squamates holds that lizards and snakes lack certain brain structures considered crucial for complex cognition (e.g., hippocampus). Mammalian brains are characterized by a layered neocortex which is involved in many cognitive processes. For a long time, the brains of birds and reptiles were considered “primitive” in comparison, with relatively large basal ganglia but no neocortex. Leaving aside the controversial question of whether a neocortex is a necessary requirement for cognition, current understanding of vertebrate brain evolution provides a radically different view. Reptiles do have a cerebral cortex. In fact, a clearly layered cerebral cortex is only found in mammals and non-avian reptiles. Moreover, it has been shown that structures once considered part of the basal ganglia of reptiles are similar, morphologically (i.e., cell types, connectivity, gene expression patterns) and functionally, to mammalian neocortex. So, although superficially different, the brains of squamates and mammals conform to a similar organizational plan that is shared by all amniotic vertebrates (Northcutt 2013).

Laterality, thought to reflect hemispheric specialization of brain function, has been described in a wide array of vertebrates. Laterality often results in behavioral asymmetries. Asymmetries in visually guided behavior seem widespread in animals with reduced inter-hemispheric connectivity and eyes that are, like those of many squamates, laterally placed. In lizards, responses to social displays during aggressive and courtship interactions have a consistent left-eye bias: visual displays elicit a stronger response when viewed from the left visual field, which is controlled by the right cerebral hemisphere. Predators are also preferentially monitored through the left eye. In contrast, prey tends to be monitored through the right eye.

## Specialized Sensory Systems and Communication

Vision and chemoreception are arguably the main sensory modalities through which squamates acquire information from the environment.

While the types of stimuli that they can detect through their visual and chemical senses have been relatively well characterized, attentional and perceptual processes remain largely uninvestigated (Fleishman and Font 2019).

Lizards and snakes have a sophisticated visual system that allows them to make fine discriminations of motion, physical form, and color. Most lizards have a simplex all-cone retina, with three to four different spectral classes of cones. Information from each cone receptor class is processed by an independent neural channel, suggesting that most lizards are tri- or tetrachromats (seeing 3–4 primary colors). Snakes show more variability, with species that have only rods, only cones, or both types of photoreceptors, and many are mono- or dichromats (1–2 primary colors). Many squamates, particularly diurnal lizards, exhibit conspicuous and elaborate color patterns that serve different adaptive functions such as camouflage, thermoregulation, warning or startling predators, and communicating with conspecifics.

Lizards and many snakes have one class of cone photoreceptor (SWS1) that is sensitive to ultraviolet (UV) light and allows them to perceive coloration patterns in this part of the spectrum. This raises the possibility that at least some squamates use a relatively private, UV-based channel to communicate with conspecifics. In support of this hypothesis, several studies have found correlations between the size or spectral properties of UV-reflecting skin patches and variables related to individual quality and/or fighting ability in male lizards (Pérez i de Lanuza et al. 2014).

Lizards and snakes also have large numbers of double cones in their retinas. Double cones are responsible for visual motion perception, which is important for detecting prey, for detecting approaching predators, and for communication. Lizards in particular have a rich repertoire of motion displays (i.e., dynamic visual signals) that involve some type of movement of the whole body or of body parts. Best known are the up and down movements of the head and/or the body (headbobs, pushups) characteristic of iguanid and agamid lizards. Males of many iguanid and agamid lizards also have an extensible throat fan (dewlap) that can be conspicuously colored. Headbob displays, often accompanied by

dewlap extension, are used primarily by males in territorial defense and courtship and convey information about the specific identity, sex, and quality of the displaying animal. Experiments using video playback of recorded displays or robotic lizards have shown that lizards are sensitive to subtle variation in motion displays. Although headbob displays are species-specific, there is considerable inter-individual variation in several aspects of the motion display which females can use to discriminate among individual males.

Rather than being fixed, the motion displays used by lizards show flexible adaptation to prevailing conditions. Wind can make plants to move, and vegetation movement can interfere with the detection of motion displays such as the headbobs of *Anolis* lizards. Two species of *Anolis* from Puerto Rico, for example, increase the speed of their headbob displays to improve communication in visually “noisy” environments of rapidly moving vegetation (Ord et al. 2007). Headbob displays in some *Anolis* begin with a series of abrupt square-wavelike movements that function as alerting components that draw the attention of receivers to the display that follows. There is also evidence that some species adjust the amplitude of the initial movements of their displays depending on the distance to the viewer. The amplitude is highest when the viewer is distant and becomes smaller as the distance to the viewer decreases (Fleishman and Font 2019).

Other motion displays involve stereotyped movements of the legs (footshakes) or the tail. Many *Podarcis* wall lizards have a repertoire of several footshake displays that are performed in different contexts and that differ in the type of movement and body posture of the displaying lizard. One footshake type in particular, labelled Type III, is directed at potential predators (including human observers) and functions as a pursuit-deterrent signal. As predicted by theoretical models, Type III footshakes are oriented toward the predator (the lizards use the leg closest to the approaching predator), they are performed more often when the predator is some distance from the lizard (not too far, not too close), and they give way to flight behavior when the predator closes in on the lizard (Font et al. 2012). Type

I foot shakes are performed after a bout of locomotion and often in the absence of obvious receivers and could thus function as a broadcast (“assertion”) display. Other footshake types are used as social signals during intra- and intersexual encounters.

Chameleons are well known for their ability to modify their body coloration to match parts of the environment. In the case of dwarf chameleons (*Bradypodion* spp.), this matching has been shown to take into account the visual capabilities of specific predators, such as birds and snakes (Stuart-Fox et al. 2008). Many lizards and snakes are not capable of rapid color changes but are nonetheless cryptically colored. To be effective, visual camouflage requires that animals choose the type of substrate that best matches their own body coloration. Experiments conducted with *Podarcis* and *Amphibolurus* show that lizards select perching and basking sites non-randomly with respect to the visual environment in order to enhance camouflage (Marshall et al. 2016; Salisbury and Peters 2019). This suggests that they assess the visual properties of available substrates and choose those with colors or patterns suitable for concealment.

Squamates have three major chemosensory systems capable of detecting biologically relevant chemicals: the main olfactory system, the vomeronasal system, and taste buds present in the tongue and in the oral cavity. Most research on squamate chemoreception has focused on the olfactory and vomeronasal systems. The olfactory system is responsible for the detection of volatile odorants, whereas the vomeronasal system specializes in the detection of relatively nonvolatile, high-molecular-weight chemicals. The tongue is an integral part of vomeronasal chemoreception, collecting airborne or substrate chemicals from the environment and delivering them to the paired vomeronasal organs located in the roof of the mouth. Tongue flicking, the quintessential squamate behavior, has been extensively used as an observable index of vomeronasal function. Inter-specific variation in the functional importance of the tongue-vomeronasal system is reflected in the size of the accessory olfactory bulbs and other structures of the accessory olfactory system.

The chemical senses allow squamates to locate potential food sources, detect and avoid predators, and communicate with others of their own species. The literature documenting the chemical discrimination abilities of squamates is immense and reveals that lizards and snakes are capable of making extremely fine-grained chemical discriminations in foraging, antipredatory, and social contexts.

Chemicals released through the skin or specialized epidermal glands allow squamates to discriminate between conspecifics and closely related heterospecifics, males and females, familiar and unfamiliar conspecifics, kin and non kin, and self-produced versus chemicals produced by other individuals. The chemicals involved are often described as pheromones even though critical evidence for a pheromonal function is often lacking. In fact, some of these chemicals allow receivers to obtain information, but there is no evidence that they have evolved for a communicative function and are thus best characterized as chemical cues. An important class of chemical cues is the signature mixtures allowing individual or group discrimination.

Dominance hierarchies, pair bonding, and extended parental care have now been described in many lizard species and offer grounds for expecting individual recognition to be widespread. Indeed, individual recognition has been often suggested on the basis of anecdotal information, but conclusive evidence for true individual recognition in lizards is limited. Males of the lacertid lizard *Podarcis liolepis* use scent marks to recognize rivals individually, evaluate their competitive ability (body size), and assess the threat posed by each individual rival neighbor (Carazo et al. 2008). This study provides the first demonstration of true individual recognition in any reptile and confirms that at least some compounds in the scent marks of male lizards function as signature mixtures rather than pheromones.

Some boids, pythonids, and viperids (e.g., rattlesnakes) possess specialized heat receptors known as pit organs on the head that allow them to detect tiny ( $< 0.05^{\circ}\text{C}$ ) changes in temperature. The heat receptors endow snakes with stereoscopic infrared vision that allows them to

accurately orient on and strike their warm-blooded prey even in total darkness. Following striking and envenomation of a prey, rattlesnakes exhibit a behavior known as strike-induced chemosensory searching. Striking presumably leads to the formation of a neural representation that rattlesnakes use as a chemical search image to locate the envenomated prey. Rattlesnakes are capable of identifying the trail left by a rodent they have themselves envenomated and distinguish it from the trails left by other rodents, even by rodents envenomated by other rattlesnakes.

Unlike snakes, which are only sensitive to low-frequency airborne sounds, lizards have ears with a wide frequency range and good sensitivity, similar to birds and mammals. However, auditory communication in lizards is limited to the relatively simple vocalizations of nocturnal geckos. Still, some lizards have been shown to use their hearing to eavesdrop on the alarm calls of birds and respond to these calls with vigilance and other antipredator behavior.

## Learning and Memory

Gordon Burghardt (1977) wrote the first major review of reptile learning. He reviewed an impressive amount of literature and criticized the then prevailing view that reptiles are instinct-driven and incapable of learning, pointing out important limitations in previous studies. More recent research has been covered in a number of updated reviews (Wilkinson and Huber 2012; Burghardt 2013, 2020).

Many tests of squamate learning conducted during the last century failed because they did not take into account peculiarities of their morphology, physiology, and behavior. Temperature at the time of testing, for example, is a crucial variable, as most lizards and snakes will not perform efficiently at temperatures that may be adequate for work with mammals and birds. As another example, food, which is a powerful reinforcer for most animals, may have little motivating effect for lizards and snakes. Since most squamates, particularly snakes, eat relatively

infrequently, using small tidbits as positive reinforcers is impractical with most species.

Studies using conditions and testing paradigms more appropriate to squamate physiology and behavior clearly demonstrate that lizards and snakes are in fact quite adept at most traditional learning tasks. But to reveal the full extent of their learning abilities requires adopting an ethological approach, i.e., to view learning from the perspective of the species' normal behavior under natural circumstances. The trick is "to make sure that the problems tested accommodate their sensory abilities and behavioural repertoires" (Burghardt 2020, p. 227; see also Roth et al. 2019).

Table 1 lists the learning types identified so far in squamate reptiles. Far from being the poor,

slow learners portrayed in the earlier literature, much recent research shows that lizards exhibit nuanced patterns of learning and memory in different contexts, such as foraging and social interactions. Demonstrations of learning in snakes, in contrast, are relatively scarce. Research conducted until the 1970s produced mixed results, largely as a result of the use of inappropriate conditioning protocols. More recent work, however, has shown that snakes clearly have the ability to learn provided that experimental paradigms and conditioning stimuli match their unique morphology, physiology, and behavior. For example, rat snakes (*Elaphe obsoleta*) show enhanced problem-solving ability in environmentally enriched conditions (Almli and Burghardt 2006), and Burmese pythons (*Python molurus*) can be conditioned to reliably depress an illuminated button in order to gain access to hidden food rewards (Emer et al. 2015).

Some authors have suggested that lizards and snakes learn in squamate-specific ways, different from birds and mammals. Suboski (1992) proposed that some forms of reptile learning conform to a variant of Pavlovian conditioning, termed releaser-induced recognition-learning, that combines the concepts of sign stimulus and innate releasing mechanism from classical ethology with the transfer-of-control version of the stimulus substitution principle from Pavlovian conditioning. However, the bulk of the evidence suggests that lizards and snakes learn in much the same way as other vertebrates; only they differ in terms of what they find easiest to learn and what motivates them to learn.

Many time-tested procedures that are routinely used in learning research with mammals or birds simply do not work with squamates. Others, however, can be extremely successful. A survey of the recent literature, for example, reveals an inordinate fondness of researchers working on lizard cognition for colored plastic lids. Following the description by Leal and Powell (2012) of a novel operant procedure requiring *Anolis* lizards to remove a colored plastic lid to access a well containing food, a slew of papers have been published that use slight modifications of the same procedure to successfully

**Squamate Cognition, Table 1** Learning types and related phenomena identified in squamate reptiles

| • Extended (long-term) memory.               |

evaluate multiple cognitive abilities in various lizard species.

Evidence for long-term memory in squamates is scarce. Aversion to prey color stimuli accompanied by discomfort generated by a LiCl injection in garter snakes disappears after 22 days (Terrick et al. 1995). A recent study found that agamid lizards can remember to avoid colors related to unpalatable prey for at least 60 days after a single aversive exposure (Ko et al. 2020). In a different context, rival recognition in aggressive encounters can affect aggressive behavior for up to 3 weeks in Australian rock dragon lizards (*Ctenophorus*) (Stuart-Fox and Johnston 2005).

## Spatial Cognition

As with other taxa, far more attention has been devoted to spatial cognition than to other types of squamate cognition (reviewed in Mueller et al. 2011). This is not surprising considering the complex spatial demands that many lizards and snakes face in their natural environment. Natural history observations and laboratory experiments clearly indicate that squamates display a range of behaviors that require considerable information-processing capabilities to solve spatial problems. Homing, exploratory behavior, and territoriality are common in species belonging to all major groups. The presence of such behaviors suggests that squamates have the ability to learn about their environment and use this knowledge in adaptive ways, to locate food or prey patches, safe refuges, or mates.

Squamates use multiple mechanisms to solve spatial problems. For example, Punzo and Madragon (2002) showed that juveniles of three species of Australian *Ctenopus* lizards are capable of learning to run a complex maze for a food reward using path integration. Mueller-Paul et al. (2012) suggested that jeweled lizards (*Timon lepidus*) navigate a complex eight arm radial maze using a stereotyped turn-by-one arm response. In both these cases, lizards relied on an egocentric (self-centered) reference frame to locate the goal relative to their own position.

In addition to egocentrically referenced mechanisms, mammals and birds are also capable of place learning, i.e., forming map-like memory representations of allocentric space which are independent of the subject's position. The possibility that reptiles, particularly squamates, may possess a hippocampus-dependent cognitive module similar to that supporting place learning in other vertebrates has attracted a lot of attention. Laboratory experiments have yielded mixed results. A study with two lacertid species did not find evidence of orientation to a single heated rock among seven unheated rocks (Day et al. 1999). However, more recent studies have demonstrated that lizards can use distal extra-maze cues to successfully navigate to a goal (Font 2019). These results suggest that lizards can use mental representations of space akin to the mental maps described in other taxa to locate a goal.

Studies with lizards and snakes have confirmed a role of the squamate hippocampus in spatial cognition. The medial cortex (MC) and the dorsal cortex (DC), the reptilian homologues of the mammalian hippocampus, are larger in actively foraging than in congeneric sit-and-wait lizards, suggesting a relationship between hippocampus size and ecological demands related to searching for spatially distributed resources. Similarly, free-ranging rattlesnakes that were repeatedly translocated had larger MC than handling or undisturbed control rattlesnakes with a smaller activity range.

## Social Cognition

Another area that has attracted considerable attention is social cognition. Squamates are often described as “asocial,” but in fact sociality in lizards and snakes is rather variable, ranging from solitary species to species that live in social networks that rival in complexity with those of birds and mammals. Although scant, the available evidence demonstrates that squamates can learn from others. In particular, recent work has shown that conspecific gaze following and social learning occur in lizards (e.g., Noble et al. 2014; Whiting et al. 2018).

Several studies with Australian skinks have tested the relationship between sociality and cognition. According to the social intelligence hypothesis, social complexity sets the stage for the evolution of complex cognitive abilities. However, results are contrary to predictions from the social intelligence hypothesis. Even solitary species are capable of social learning, and social isolation does not affect performance in cognitive tasks in the more social species. This evidence suggests that a complex social structure is unnecessary for animals to learn effectively from conspecifics, and the link between social behavior and cognition remains tenuous, at least in this group.

## Concluding Remarks

Most studies of squamate cognition fall into one of two types. Some studies have as their main goal to explicitly test what cognitive abilities previously described in other groups (usually birds and mammals) are also present in squamates. Others are not specifically concerned with the assessment of cognition *per se* but use a learning paradigm to explore an ecologically or ethologically relevant question. A challenge for studies of the first type is to avoid falling into the trap of considering that proficiency in a given task necessarily implies shared mechanisms across different taxa. A recurrent theme in comparative cognition studies is that functionally similar behavior can be produced by different mechanisms in different animals. Moreover, behaviors that appear to reflect complex cognition can arise from “simple” associative learning that some researchers would not even consider cognitive. Unfortunately, few studies of squamate cognition address the mechanisms underlying their subjects’ performance (Font 2019).

Some cognitive abilities have not been reported in squamates. Cross-modal recognition (the ability to transfer information across sensory modalities), for example, has been described in mammals, fish, and invertebrates, but not in reptiles. The evidence for concept formation is at best

anecdotal, and metacognition, a hot topic in contemporary comparative cognition research, has never been investigated in squamates. What should we make of this lack of evidence? In the past there has been a tendency to equate absence of evidence with evidence of absence; a more sensible alternative seems to be to use the lack of evidence to identify areas that need more exploration.

Squamates are notoriously difficult subjects to work with, particularly in a laboratory setting. When their cognitive abilities are tested, it is often with a relatively small number of species that are less challenging to maintain in artificial conditions. A consequence of the sparse phyletic coverage is that there are no relevant studies for entire families or even for larger groups, such as amphisbaenians. In addition, many cognitive studies with squamates use small sample sizes, resulting in low statistical power that compromises the ability to reach meaningful conclusions.

Another problem has to do with the way performance is assessed in learning experiments. Studies of learning and memory depend critically on the researcher’s ability to determine if and when a given task has been acquired. For many reptiles, including lizards and snakes, the learning period in an experimental situation is often protracted, either because learning tasks are difficult or the experimental procedure is inappropriate for the animals. In these situations, the researcher is faced with long strings of correct and incorrect responses and may have difficulty determining the starting and ending points of learning. The standard criteria used by many researchers to assess performance in experiments with repeated trials are based on ad hoc testing for non-random responses (loosely based on the binomial distribution, e.g., 2/3 correct choices for two successive testing sessions) or runs tests for unblocked trials (successive correct choices). However, these statistical techniques typically assume that individual trials are independent and that each block of trials follows a binomial distribution. Both of these assumptions are often unrealistic.

But the main problem with studies of squamate cognition continues to be the dearth of

experimental designs with real ethological validity: there is an urgent need for the development of testing paradigms more appropriate to squamate physiology and behavior than those traditionally used with mammals or birds. There is also a need for more field tests of cognitive abilities. By studying free-ranging lizards and snakes in the wild, researchers can potentially assess the cognitive skills of large numbers of individuals, without the need to place subjects in artificial or alien environments that can affect their behavior, and under the very conditions in which those skills evolved (Steinberg and Leal 2018).

This entry has reviewed key examples of the behavioral and cognitive complexity of squamate reptiles. Many more could not be included due to space limitations (e.g., personality, parental care, play, etc.). In light of the available evidence, there can be no justification for considering that lizards and snakes are instinct machines with little scope for cognition and learning; instead the existing literature shows that they have considerable behavioral flexibility and can cope with unusual challenges that could not be dealt with adaptively using only hardwired responses.

The study of squamate cognition may also provide insight into a long-standing evolutionary puzzle. The cognitive similarities between birds and mammals, particularly primates, are thought to be, given the large phylogenetic gap separating these two groups, the result of convergent evolution. This reasoning, however, is based on the assumption that cognitive abilities similar to those of birds and mammals are entirely lacking in reptiles, the modern descendants of the ancestors of all amniotic vertebrates. This assumption is, given the evidence reviewed here, unfounded. Nonetheless, further studies are required to unravel the many questions that remain open about squamate cognition.

## Introduction

The non-avian reptiles comprise about 10,800 living species allocated in the clades Archosauria (crocodilians), Testudines (turtles), and Lepidosauria (tuataras and Squamates). Squamata includes Amphisbaenia (amphisbaenians), Sauria (lizards), and Serpentes (snakes) and is among the most diverse radiations of terrestrial vertebrates with more than 10,400 taxa occupying habitats from tropical oceans to temperate mountain summits (Uetz et al. 2020; Vitt and Caldwell 2009).

Squamates occur on every continent except Antarctica and exhibit distinct body forms and habits, being mainly terrestrial or arboreal, although many snakes are semiaquatic, spending much of their lives in or immediately adjacent to freshwater, or, less commonly, in estuaries and seawater (Lillywhite 2014; Uetz et al. 2020; Vitt and Caldwell 2009). Amphisbaenians are adapted to a burrowing lifestyle, with about 190 species distributed in southern Europe, northern Africa, Asia Minor, and South America (Pianka and Vitt 2003; Uetz et al. 2020). They have an elongated body with short and stubby tails, scales arranged in rings around the body, being mostly limbless, with the exception of three species within the family Bipedidae (Vitt and Caldwell 2009). Unfortunately, the ecology and life history of

amphisbaenians are poorly known due to their fossorial lifestyle and the scarcity of researchers studying the group (Pianka and Vitt 2003).

The snakes clade has about 3,700 extant species (Uetz et al. 2020) divided into two large groups: Scolecophidia and Alethinophidia. Scolecophidia is a group of about 450 species of small-sized fossorial snakes feeding on ants and termites (Cundall and Greene 2000; Uetz et al. 2020). Alethinophidia, on the other hand, encompasses the remaining species and shows a wide array of size and diet, with species capable of ingesting relatively large prey (Cundall and Greene 2000). Snakes have a peculiar tube-shaped body with a head and a tail; locomotor members are absent (Lillywhite 2014). They are distributed on all continents, except Antarctica, occupying a wide variety of habitats (from desert to marine areas), habits (from fossorial, cryptozoic, to semi-arboreal and arboreal), and feeding on a plethora of prey, from small invertebrates to large mammals (Lillywhite 2014; Vitt and Caldwell 2009).

Lizards belong to paraphyletic group, most species of which have four well developed limbs and an elongate tail exhibiting a remarkable morphological diversification, ranging from few centimeters in length, such as chameleons and geckos, to nearly three meters long, as the varanid lizard, Komodo dragon (Pianka and Vitt 2003). Lizards comprise more than 6,600 extant species occurring in all continents except Antarctica, and on most oceanic islands (Pianka and Vitt 2003; Uetz et al. 2020). This widespread distribution denotes their broad ecological, physiological, and behavioral adaptations to hot and cold climates, to extremely arid, to freshwater or marine habitats, and to lowland to high elevation regions (Pianka and Vitt 2003; Vitt and Caldwell 2009). Furthermore, the group shows a wide array of feeding habits, most of them being predators with species feeding on small invertebrates to large mammals (Pianka and Vitt 2003). Many lizards, including some representatives of iguanids, are herbivores, with adults feeding on different plant portions like flowers, leaves, stems, and fruits (Pianka and Vitt 2003).

## Sexual Dimorphism

Sexual dimorphism is defined as phenotypic differences between males and females of a species, and is frequently associated with sexual selection (Andersson 1994; Kratochvíl and Frynta 2002). In squamate species showing male–male combat, males should be the larger sex (Shine 1994) and show overdeveloped organs related to combat or advertisement display (Kratochvíl and Frynta 2002). Males of many species of lizards and some snakes exhibit direct physical combat (Kratochvíl and Frynta 2002; Shine 1994), or engage in threat displays with no physical combat or risk of injury, such as push-up displays, chemical signals, or advertisement sounds (Pianka and Vitt 2003). Many species of lizards also exhibit sexually dimorphic ventral glands producing waxy secretions or differentiated staining pattern (Kratochvíl and Frynta 2002; Pianka and Vitt 2003). In general, male lizards are larger, brightly colored, and have more ornamentations than females, although exceptions are not rare (Pianka and Vitt 2003). The males of the South American Teiidae, *Dracena guianensis*, have a much larger head and jaw muscle than females, to the point that they look almost disproportionate (Pianka and Vitt 2003). Many species of lizards are territorial; males establish and defend territories from other males by different behaviors. The male rainbow lizards, *Agama agama*, can change nearly instantaneously from gray to bright blue when encountering another male as a warning for territorial invasion, which is often followed by head bobbing and fighting (Pianka and Vitt 2003). Some male geckos (Gekkota) also use calls to maintain territories by advertising ownership, establishing dominance, and attracting females (Pianka and Vitt 2003). In most snakes, females are larger than males (Shine 1994); this feature is considered adaptive since it allows the development of more and/or larger offspring (Rivas and Burghardt 2001). Different from lizards, there are very few records of territorial snakes, and male–male fighting is also uncommon (Rivas and Burghardt 2001). One well-documented case of territoriality in snakes occurs in the nocturnal small-eyed snake,

*Cryptophisnigrescens*, in which males defend basking sites from rival males. In this species, males engage in ritualized combat and attain larger body size than females (Webb et al. 2015).

Although territorial behavior and male–male fighting in snakes is uncommon (Rivas and Burghardt 2001), distinct male–male combat behaviors were listed for snakes, such as (1) body bridge, the formation of a high vertical arc with a section of the body; (2) coil, when one snake coils around the other, or both coil around each other, at least anteriorly; (3) closed-mouth strike, when one snake strikes at another, with its mouth closed; (4) downward push, when both snakes have the anterior portions elevated, often coiled around each other, and attempt to push the other toward the ground; (5) head raise, when the snake elevates its head and much of its anterior body portion off the substrate; (6) jerk, the snake gives a sudden, staccato jerk with the head; (7) spur poke, when one snake pokes another with the spurs; and (8) sway, the snake sways its neck back and forth with the anterior portion of the body elevated (Senter et al. 2014).

## Copulatory Organs

All squamates exhibit internal fertilization with males showing a pair of intromittent reproductive organs, the hemipenis, used to deposit spermatozoa into female's cloaca. These structures are located at the base of the tail and are everted from openings in the posterior part of the cloaca by vascular pressure (Vitt and Caldwell 2009). Only one hemipenis is everted and used during copulation, being inserted into the female internal genitalia, which lie above the cloaca and have the oviducts outlets in the end of the urodeal corns. Once the copulation is completed, a retractor muscle withdraws the hemipenis (De-Lima et al. 2019; Vitt and Caldwell 2009).

The hemipenis are known to exhibit considerable variation in shape, dimensions, and ornamentation. Some authors have associated limb reduction of snakes and some lizards to their calcified hemipenial spines, implying that in the absence of well-developed limbs, the hemipenial

calcified ornaments (spines and spicules) could take on the role of keeping male and female tightly attached while mating (Nunes et al. 2014). The hemipenial morphology of Gymnophthalmidae lizards was assessed to test the phylogenetic correlation between limb reduction and the presence of calcified hemipenial spines and showed that hemipenial ornamentation may be related to couple-anchoring in some limbless squamate lineages, but do not represent the single mechanism that keeps male and female attached during mating, since basal snake lineages, all known amphisbaenians, and several limb-reduced lizards lack any traces of calcified spines or spicules. Alternatively, many species of snakes and lizards with limb reduction and nude hemipenis can use their tail in the couple-anchoring process (Nunes et al. 2014).

The most direct mechanical interaction between males and females with internal fertilization occurs during copulation, implying morphological coevolution of genitals (Brennan 2016). One hypothesis for the evolution of internal fertilization is that during evolutionary history, females retained mature eggs to decrease the risk of desiccation and predation, selecting males to evolve an intromittent organ to inject spermatozoa inside the female (Brennan 2016). Another hypothesis is that the intromittent organ could have evolved as a way of trying to gain fertilization of eggs before their release, increasing reproduction success (Brennan 2016). Studies of Squamata reproductive organs are usually focused on male hemipenis; however, some authors began investigating the homologous internal paired structures in females, called hemiclitores, and explored the coevolution of these structures in male and female of the same species (Siegel et al. 2011; De-Lima et al. 2019).

The correlation between the conspecific genitalia morphology and the differences from genitalia structures of other species could be the result of reproductive isolation mechanisms (Siegel et al. 2011). The presence of the lock-and-key mechanism in squamate genitalia has been studied, species in which males exhibit long hemipenis with few spines; the females' cloaca are highly bilobed with a very thin wall, while short hemipenis with

many spinines are associated with females exhibiting short cloaca with a very thick wall (Siegel et al. 2011). For instance, a group of researchers inflated the hemipenis of the snake *Thamnophis radix* inside the female genitalia in order to observe interaction of morphological features of both male and female genitals. The study showed the shape of the hemipenis works as a key-lock mechanism with the vaginal pouch (Brennan 2016). Furthermore, the study found the large hemipenis spines were embedded in areas of the female vaginal pouch with more loose connective tissue, which probably minimized the damage caused by the spines (Brennan 2016).

A study regarding the genital morphology of the lizard *Tropidurus torquatus* argues that males with large hemipenial lobes would benefit from increasing the ability to better stimulate the urodeal glands of females, a region with phagocytic function acting as a physiological barrier in spermatozoa selection. The stimulation of these glands induces the production of a secretion that functions as a mechanical and/or biochemical barrier for future copulation semen to fertilize the eggs (De-Lima et al. 2019).

## Courtship

As demonstrated, the shape of the hemipenis may be affected by sexual selection forces, in which males with a specific morphology may be more successful in copulation (De-Lima et al. 2019). However, these forces not only seem to shape complex reproductive organs, but also may impose selection on complex behaviors (Senter et al. 2014). Studies on reproductive behavior of Squamata show that many species can use different strategies of courtship to acquire mates (Pianka and Vitt 2003; Senter et al. 2014).

Distinct courtship behaviors of snakes are listed in the literature, such as (1) bite, when one snake strikes another; (2) chin-rub, a snake draws its chin along the skin of another specimen; (3) cloacal gaping, a snake promotes a wide cloacal opening; (4) lateral punch, when one snake laterally slams its body against the body of

another snake; (5) mounting, a snake presses down on another individual; (6) spur rub, one snake rubs another with the spurs; and (7) tail quiver, when a snake continuously vibrates the tail (Senter et al. 2014).

Courtship has also been reported for lizards. The Bengal monitor, *Varanus bengalensis*, has a complex courtship ritual involving visual, chemical, and tactile communication. Visual cues help males locate the female, chemical signals allow identification of species and sex, and tactile cues stimulate the female (Pianka and Vitt 2003). The male of the green iguanas, *Iguana iguana*, approaches other males and females in a similar way, performing some head bobs. On the basis of the reaction to his head bob, he either initiates an aggressive interaction against another male or courtship toward a female. In courtship, both male and female perform vibratory head bobs, after which the male approaches the female, moves his head across her neck, then bites her neck skin. While holding on to the skin, the male steedles the female, and tries to lift her tail with his own. The female eventually raises her tail, then the male inserts one of his hemipenis. If the female is not receptive, she will reject the male with a head-swing display during the early stages of the encounter (Pianka and Vitt 2003). Besides that, expansion of throat pouch and head-bobbing have also been described as courtship behavior of many species of lizards (Pianka and Vitt 2003).

In territorial lizards, where the male's quality is directly related to the territory he holds, prolonged courtship behavior may not occur (Pianka and Vitt 2003). Within non-territorial lizards, other factors assume importance to determine the highest-quality male around. By prolonging courtship, the female has an advantage, giving the highest-quality male opportunity to displace any other males pursuing her (Pianka and Vitt 2003). The male broad-headed skink, *Eumeces laiceps*, follows the female for as much as 3 days before mating, and after, he often guards their mates against other males to ensure paternity (Pianka and Vitt 2003). An interesting complex social behavior occurs in the Australian skink *Tiliqua rugosa*. Most adult females remain with a single male for long time periods, not only for the

breeding season but also, apparently, during the following years. Analysis of DNA evidence for *T. rugosa* suggests that, even though monogamy predominates among this species, polygyny occurs at low levels (Pianka and Vitt 2003).

There are few studies focused on the female–male sexual interaction of amphisbaenians, probably due to their fossorial lifestyle. However, studies of semiochemicals produced by precloacal glands in intraspecific communication and chemosensory sex recognition of the amphisbaenian *Blanus cinereus* showed that, according to behavioral responses to the scent of conspecifics, amphisbaenians are capable of detecting and discriminating between scent of conspecific males and females by using chemosensory clues (Pianka and Vitt 2003).

## Fertilization

After copulation, spermatozoa reach the surface of an egg. The head of the spermatozoon contains the cell nucleus capped by an acrosome that produces proteolytic enzymes able to digest the egg capsule (Vitt and Caldwell 2009). This process allows the spermatozoon to penetrate into an egg. After this, the pronucleus moves into the cytoplasm of the ovum (Vitt and Caldwell 2009). Next to the input of a spermatozoon, the vitelline membrane of the ovum detaches, lifting all other spermatozoa from the surface of the ovum (Vitt and Caldwell 2009). Fertilization occurs when the two pronuclei fuse, triggering the process of egg conversion into an embryo through successive divisions into smaller cells (Dowling and Zug 2020; Vitt and Caldwell 2009).

## Sperm Storage

Copulation and the deposition of spermatozoa into a female's reproductive tract can occur before the eggs are matured. The time between mating and fertilization in reptiles varies significantly, ranging from hours to years, depending on the species. This variation occurs because females of some species can store spermatozoa and use these

to fertilize eggs long after mating (Blackburn 1998; Dowling and Zug 2020). The ability to store spermatozoa in the oviduct has evolved and has been widely documented in squamate species, many with special structures for maintenance of the spermatozoon (Blackburn 1998; Eckstut et al. 2009). Oviductal sperm storage has allowed the separation of oogenesis, ovulation, and fertilization from mating activity, both temporal and geographically (Blackburn 1998; Eckstut et al. 2009). Spermatozoa storage in reptiles may be a physiological need due to ectotherm, long reproductive cycles, and as an insurance against not finding a partner (Birkhead and Møller 1993). It also provides some advantages in life history strategies: several clutches may be fertilized with no need of successive matings, which is especially important in events of colonization of new habitats (e.g., a single female is sufficient to colonize an island, Eckstut et al. 2009). Sperm storage also provides the conditions for sperm competition, allowing post-mating mechanism for sexual selection, since this behavior increases the opportunities of females to obtain the best-quality genes (Birkhead and Møller 1993).

## Parthenogenesis

Among all vertebrates, the only group that has evolved natural parthenogenesis is the Squamata (Kearney et al. 2009; Fujita and Moritz 2009). In that kind of parthenogenesis, also known as obligate parthenogenesis (Booth and Schuett 2016), mothers produce unreduced and genetically identical daughters with no need for males or spermatozoon for fertilization (Fujita and Moritz 2009). There are 40 known cases of obligate parthenogenesis, mostly from lizard species (Kearney et al. 2009) out of 11,050 currently recognized reptile species (Uetz et al. 2020). They are almost always of hybrid origin, but some are suggested to have a spontaneous or nonhybrid origin (Kearney et al. 2009; Fujita and Moritz 2009). The New World Gymnophthalmidae lizard, *Leposomaper-carinatum*, and the Teiidae *Ameivulanativo* are examples of unisexual parthenogenetic species

(Kearney et al. 2009; Uetz et al. 2020). Parthenogenesis has never been recorded in amphisbaenians. The only documented case of obligate parthenogenesis in snakes is a single Typhlopidae species, *Indotyphlops braminus*, the Brahminy blind snake (Booth and Schuett 2016). Facultative parthenogenesis, asexual reproduction in an otherwise sexually reproducing species, has been documented in several species of snakes and lizards (Booth and Schuett 2016). The Komodo dragon, *Varanus komodoensis*, and the Burmese python, *Python molurus bivittatus*, are well documented cases of facultative parthenogenesis in Squamata (Kearney et al. 2009).

## Viviparity

After fertilization, Squamata shows different strategies associated to embryo development, such as oviparous (egg laying) and viviparous (live bearing). Estimates have pointed out that nearly 20% of the squamate species are viviparous. However, viviparity has arisen independently several times (>115) along the evolutionary history of this group of reptiles, more often than any other clade of vertebrates (Blackburn 2015). Therefore, squamates provide a unique model for studies on the transition from oviparity to viviparity in amniote vertebrates (Blackburn 1998; Murphy and Thompson 2011). The evolution of viviparity has significant effects for life history strategies of this taxon, including a great diversity of placental functions, structures, and modes of embryonic nutrition (Blackburn, 1998; Murphy and Thompson 2011). The great majority of viviparous squamate are *lecithotrophic*, meaning that most nutrients for embryonic development are supplied by the yolk. Very few lizards and no snakes are known to be substantially *placentalotrophic*, with placental membranes supplying large quantities of nutrients for development (Blackburn 1998). Some groups of matrotrophic lizards, such as the New World *Mabuya* and other closely related genera, as well as the Afro-European *Chalcides*, both Scincidae, show strongly convergent placental features with eutherian mammals. The same kind of embryonic nutritional structure has evolved

independently among eutherian mammals and in these two reptilian groups (Blackburn 1992). Some species of Squamata are reported to contain both oviparous and viviparous representatives like the Australian Scincidae *Lerista bougainvillii* and *Saiphosequalis*, and the European Lacertidae *Zootoca vivipara* and the South American water snake of the tribe Hydropsini *Helicops angulatus* (Blackburn 2015).

## Parental Care

Parental care can be defined as any action of the parents, after laying eggs or parturition, that increases the chances of survival of the offspring (Shine 1988). Traditionally, it is considered absent in most reptiles, excluding Archosauria (Shine 1988). Among Squamata, this behavior is exhibited by some species of lizards and snakes (Shine 1988). Factors such as seasonality, breeding season, food supply, and predation pressure may have influenced the evolution of different modes of parental care (Huang and Wang 2009).

In general, parental care can be characterized by some type of assistance given to eggs or neonates by one parent or both (Shine 1988). The presence of the parents probably represents protection against predation, pathogens, and dehydration (Shine 1988). Care for eggs means that parents stay close to the eggs for some time after oviposition and some type of manipulation or protection of the nest may occur (Shine 1988). Care for the neonates consists of providing some assistance to the newly born or newly hatched (Shine 1988).

Care is exclusively provided by females in Squamata (Reynolds et al. 2002). The probable explanation may lie in the time between copulation and oviposition or parturition (Reynolds et al. 2002). After copulation, males generally disperse to search for new sexual partners while females leave males' territory and look for places to establish their nests (Reynolds et al. 2002).

Four categories of parental care are known in Squamata: (1) female buries eggs and exhibits some behavior to defend the nest; (2) female

coils around the eggs, producing heat through muscle contraction (shivering thermogenesis), and consequently warming the eggs; (3) female stays close to the eggs for some time after oviposition; and (4) female aids neonates (Shine 1988).

The most widespread strategy of parental care among Squamata is for the female to stay close to the eggs after oviposition (Shine 1988). The defensive behavior of the nest against predators is known in some taxa and the intensity of the defense is variable (Shine 1988). There are reports in the literature of defensive behaviors ranging from aggressive interactions in lizards and snakes, up to abandonment of the nest depending on the type of predator in some species of lizards. These issues indicate that the time invested in parental care may be influenced by the type of predator and the maternal defense capacity (e.g., Greene et al. 2002; Huang and Wang 2009).

Parental care must meet critical demands for the development of offspring (Stahlschmidt and DeNardo 2009). Egg brooding by shivering thermogenesis seems to be widespread in python snakes, whose embryos normally develop at temperatures close to 30 °C (Shine 1988). During the incubation of eggs, the snake coils around the egg mass producing heat through rhythmic muscle contractions, maintaining a relatively high and constant temperature (Shine 1988). In addition, they are capable to make behavioral adjustments to improve the thermal microenvironment of the egg mass: females tend to spend more time and more tightly coiled around the eggs when environment temperature is lower (Stahlschmidt and DeNardo 2009).

Finally, some records of parental care invested in newborns or young are known among Squamata (Shine 1988). Some forms of care consist of providing assistance during hatching, building shelter for protection, and displaying aggressive defensive behavior against possible predators (e.g., Greene et al. 2002). There are 33 species of vipers that exhibit protective behavior for the offspring and some even remain with the young for several days until the first cycle of ecdysis (Greene et al. 2002).

## Reproductive Endothermy

A recent study has demonstrated the occurrence of seasonal reproductive endothermy in the tegu lizard *Tupinambis merianae*, a species with a circannual cycle alternating between an active period during spring and summer, which coincides with the breeding season, and a period of dormancy during most of autumn and winter (Tattersall et al. 2016). This species has a diurnal habit and thermoregulates by basking in the sun and takes shelter retreating to burrow at night (Tattersall et al. 2016). The body temperature of *T. merianae* remains stable relative to the temperature of the burrow when the animal is at rest (Tattersall et al. 2016). However, in the breeding season, the body temperature of these lizards is substantially higher than the temperature of their shelters (Tattersall et al. 2016). In an experiment in which groups of individuals were subjected to different environmental conditions for long periods, body and environmental temperatures, in addition to metabolic rates were monitored and compared. The results showed that individuals of this species were capable of maintaining a differential body temperature in relation to the environment during the breeding season, probably sustained by endogenous heat production due to the high metabolic demands of reproduction. This finding is the only one record of reproductive endothermy in reptiles (Tattersall et al. 2016).

## Growth

Historically reptiles were considered to exhibit indeterminate or attenuated growth, meaning that these animals grow rapidly when young and at a slower rate after reaching sexual maturity. This rate reduction occurs mainly because, once such organisms reach sexual maturity, a significant fraction of metabolic rate is devoted to reproduction (Sebens 1987; West et al. 2001). Nevertheless, current literature shows that many squamate probably exhibit determinate, or asymptotic, growth having a period of rapid juvenile growth that slows down upon reaching full adulthood and

ceasing altogether a few years after maturity (Dowling and Zug 2020; Frýdlová et al. 2019).

Studies focusing on growth plate cartilage in the epiphysis of long bones of the Iguania clade, comprising Acrodonta (agamas and chameleons) and Pleurodonta (“iguanas”), showed that growth plate cartilage was absent in most of the examined adults of Pleurodonta, while this cartilage was preserved in most of the adult specimens of Acrodonta (Frýdlová et al. 2019). Considering that growth plate cartilage is responsible for longitudinal skeletal growth by the process of endochondral ossification, the absence of this structure in Pleurodonta may be interpreted as an irreversible arrest of skeletal growth, pointing that this group has determinate growth (Frýdlová et al. 2019). On the other hand, the persistence of growth plate cartilage in Acrodonta suggests that this group shows indeterminate growth (Frýdlová et al. 2019). Therefore, these findings reject the universality of indeterminate growth in lizards and acknowledge some degree of plasticity in squamate body growth, which is probably affected by distinct ecological and life history strategies (Frýdlová et al. 2019).

Due to the great diversity of species, habits, and sizes, information on squamate longevity is extremely variable. In general, the bigger the animal, the longer its longevity (Dowling and Zug 2020), with large snakes and lizards living more than 20 years (Dowling and Zug 2020).

## Synonyms

Snake, lizard, or worm lizard locomotion

## Definition

Movement used by snakes, lizards, and worm lizards to traverse their environment.

Squamata is comprised of lizards, snakes, and amphisbaenians (worm lizards), and with over 10,000 species, is the largest order of living tetrapods and second largest order of vertebrates. The squamates receive their name from their scaly skin, which varies considerably in morphology (Vitt et al. 2003). They are found almost worldwide and are incredibly adept at surviving and proliferating as introduced species (Krysko et al.

2011; Vitt et al. 2003). Their success may in part be due to their diversity of locomotor specializations (e.g., burrowers, gliders, bipedal runners, climbers, and arboreal specialists) or extreme body size range. Limblessness is common in squamates and is thought to have evolved multiple times independently (Gans 1975).

## Major Locomotor Modes

*Squamate locomotion* can be broken down generally into limbed versus limbless movement. Accordingly, this chapter will discuss these movement patterns in reference to the lizards and snakes, respectively. A review of worm lizard locomotion is beyond the scope of this chapter. Terrestrial gaits in the squamates are characterized by considerable inter-cycle variation in both limb-loading and timing (Granatosky et al. 2020). All walking gaits in lizards are symmetrical and involve two general patterns in which animals move their limbs (Granatosky 2018; McElroy et al. 2008). A lateral-sequence gait is one in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb).

A diagonal-sequence gait is one in which each hindlimb footfall is followed by a contralateral forelimb footfall (i.e., right hindlimb, left forelimb, left hindlimb, right forelimb). Commonly, during walking gaits, the forelimbs and hindlimbs are traveling together as a slightly asynchronous couplet. When the ipsilateral forelimbs and hindlimbs are traveling together, this is referred to as a lateral-couplet; when the contralateral forelimbs and hindlimbs are traveling together, this is referred to as a diagonal-couplet. Very rarely do the limbs move together in perfect synchrony (Cartmill et al. 2002).

Almost all lizards use a lateral-sequence diagonal-couplet footfall pattern (McElroy et al. 2008; Fig. 1). This footfall sequence is inherently quite stable due to the generally low proportion of the stride spent as a unilateral bipod (~22%) and the relatively high proportion of the stride spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed limbs in contact with the support). In general, foot positions arranged as diagonal bipods and large tripods are thought to be highly stable (Cartmill et al. 2002). In contrast, some highly arboreal chameleons tend to use a diagonal-sequence diagonal-couplet footfall

**Squamate Locomotion,**  
**Fig. 1** “Hildebrand” plot displaying diagonality against hindlimb duty factor collected during quadrupedal walking in squamates (n = 43 species)

patterns when moving along relatively thin arboreal supports (Cartmill et al. 2002). This gait pattern maximizes the proportion of the stride in which the limbs are arranged as a widely splayed diagonal bipod and ensures that one of the grasping hindfeet is placed in a protracted position (and thus lies roughly underneath the animal's center of mass) on a tested support at the moment when the contralateral forefoot strikes down on an untested support during arboreal locomotion (Cartmill et al. 2002).

Literature on gait transitions (a speed related switch from walking to running) in lizards is scant and it does not appear that lizards can adopt asymmetrical running gaits (e.g., gallop or bound). Experiments on teiid and iguanid lizards revealed that gait transitions are not visually detectable based on limb phase definitions (Irschick and Jayne 2000). Instead, duty factor just continues to decrease with speed until eventually diagonal-couplet walking becomes a diagonal-couplet run (Irschick and Jayne 2000). However, if one bases the definition of a gait transition off of center of mass movements rather than limb phase definitions, then both walking and running center of

mass movements are present (Reilly et al. 2006). It should be noted, the use of these walking and running center of mass movements are not speed dependent (Reilly et al. 2006), and therefore are not synonymous with the gait transitions observed in birds and mammals (Granatosky et al. 2018).

While typical lizard locomotion is quadrupedal, bipedal running is observed in numerous species (Irschick and Jayne 1999; Snyder 1949; Fig. 2). Most notable is the common basilisk (*Basiliscus basiliscus*) that can maintain bipedal gaits while running on top of the water's surface (Snyder 1949). Bipedality usually occurs when a lizard with longer hind than front limbs accelerates to running speed. During bipedal locomotion, the forelimbs leave the ground and the trunk of the lizard is elevated. Only the hindlimbs power movement (Irschick and Jayne 1999; Snyder 1949). There seems to be no speed or cost advantage to bipedal locomotion over quadrupedal locomotion (Clemente et al. 2008).

Unlike mammals and birds, lizard locomotion is characterized by a sprawling posture. Sprawling postures are those in which the humerus and femur cannot attain an orientation with their long

**Squamate Locomotion, Fig. 2** Lizards and snakes can accomplish an impressive range of locomotor behaviors including (A) quadrupedal and (B) bipedal running and

multiple forms of (C) limbless locomotion. As such, squamate locomotion has served as a basic design for numerous (D) bio-inspired robotics

axes vertically directed. Limb movements during sprawling gaits are complex and limb posture changes considerably during a stride (Brinkman 1980; Irschick and Jayne 1999; Reilly 1995; Sullivan 2010). Rather than moving in a fore-aft arc underneath the body, the humerus and femur move backwards, outwards, and downwards during stance phase (Brinkman 1980; Russell and Bels 2001; Sullivan 2010). Such movements complicate the operation of the distal limb segments and dictate their relative effectiveness during propulsion (Granatosky 2020; Sullivan 2010). For sprawling lizards, the highly abducted limb and lateral rotation of the zeugopod relative to the autopod results in a kinematic arrangement in which the ankle and wrist flexor musculature are not in line with the travel path at the end of stance phase (Brinkman 1980; Irschick and Jayne 1999; Reilly 1995; Russell and Bels 2001; Sullivan 2010). The varanids have modified their calcaneal morphology with an expanded lateral “heel”. This structure allows *m. peroneus longus* to serve a propulsion function during locomotion (Granatosky 2020; Sullivan 2010).

Lateral body undulation plays an important part in lizard locomotion and is integrated with limb movement (Russell and Bels 2001). Standing wave patterns, where points of no lateral bending nodes alternate with areas of maximal bending internodes, are clearly developed in forms with stoutly developed limbs (Russell and Bels 2001). However, this pattern is speed related, and the standing wave of lateral bending at low speeds is replaced by a traveling wave of bending as velocity increases. The travelling wave patterns, where points of maximal bending pass down opposite sides of the body alternately from anterior to posterior, are most clearly developed in limbless terrestrial forms (Gans 1975). Highly arboreal lizards limit lateral spine bending during locomotion arguably to increase stability on thin supports (Fischer et al. 2010).

Locomotion in snakes, and other limbless species, essentially use these same kinematic patterns of lateral body undulations but modify the basic motor pattern (Jayne 1988a). As with lizards, lateral undulation in snakes involve waves of lateral bending that are propagated via large dorsal

muscles are activated sequentially along the body from head to tail. As the snake’s body encounters structures along its path, it exerts force against it and deforms locally around it. As the snake pushes against multiple points of contact simultaneously, the lateral force vectors cancel each other, leaving a resultant vector that propels the snake forward. Rapid sensorimotor feedback allows for postural adjustment around each object that gives the snake even finer control over the direction of force exertion. When startled, or moving across smooth surfaces, it is often the case that the snake’s body slips across the substrate. To generate forward propulsion, irregular bends of the body and tail press vertically on the surface at different points allowing the animal to push down with enough force to move the center of mass (Gans 1975; Jayne 1986).

Beyond serpentine undulation, snakes have come up with other locomotor modalities to traverse their environments (Jayne 1986). Most similar is sidewinding, which is used when the substrate fails to provide a rigid frictional base (e.g., sandy soils). In sidewinding, only two parts of the body are in contact with the ground simultaneously. With the head and tail firmly anchoring the snake, it throws its body forward in a loop. When that portion lands, the head is thrust forward, followed quickly by the tail. This pattern is repeated to generate forward motion. Muscle activity during sidewinding is like that in lateral undulation except that some muscles are also active bilaterally in the regions of trunk lifting (Jayne 1988b; Secor et al. 1992). Concertina locomotion involves positioning the body into a series of bends and then straightening out the anterior portion of the body while anchoring the posterior half. As the anterior portion gains solid traction with the substrate, the posterior portion of the snake is then pulled forward. The repeated pulling and pushing of static body portions allow snakes to move through narrow passages and climb (Dial et al. 1987; Jayne 1988b; Jayne and Davis 1991). Finally, rectilinear locomotion involves the ventral scales being lifted slightly from the ground and pulled forward, and then pulled downward and backward. Such motion, occurring simultaneously at several points along the body, allows the snake to move forward in a linear path without lateral

undulation of the body. Rectilinear locomotion locomotor mode is observed most often in large-bodied snakes (Lissmann 1950; Marvi et al. 2013).

## Influence of Squamate Locomotion on Bio-inspired Robotics

Perhaps because lizards and snakes can accomplish an impressive range of locomotor behaviors driven largely by neuromuscular modifications rather than anatomical, *squamate locomotion* has served as a basic design for numerous bio-inspired robotics (Liljebäck et al. 2012; Ma 2001; Menon et al. 2004; Fig. 2). This chapter will discuss two examples. The sticky-bot is a gecko-inspired robot that implements the directional adhesive nature of a gecko's feet to climb walls. Geckos climb walls in an interesting fashion that are not merely predicated on chemical adhesion, like that of tape, but a phenomenon that is known as directional adhesion. This comes about in nature as a gecko's feet are covered with what are called setae. Setae are tiny hairs that are about one-twentieth the width of a human hair. The setae themselves branch into hundreds of even smaller hairs called spatulae. These hairs cling to surfaces through many molecular interactions called van der Waals forces. These forces summed up over all the tiny hairs provide enough force to support the gecko's weight while still allowing for the gecko to detach its feet easily from the surface and sustain its locomotion (Menon et al. 2004).

The challenge of designing these sticky-bots comes in designing this directional adhesive functionality into the feet allowing the robot to achieve this mode of vertical locomotion. Stanford University has developed its sticky bot that uses synthetic setae to replicate this directional adhesion which allows geckos to climb surfaces. Although this synthetic material does not replicate the same adhesive action as the feet of a gecko, it has worked quite well. This material is a rubber-like substance with microscopic polymer hairs that are very similar to the hairs on the feet of a gecko. These polymer stalks are 30 micrometers wide, angled, and have oblique tops, allowing for them

to have directional adhesion. Stanford also designed their sticky-bot with the intricate movements that geckoes make in their wall-climbing process and their curly toes into account in their design. This robot is quite successful at vertical movement but can only climb very smooth surfaces like glass. A sticky-bot developed by Carnegie Mellon University is able to climb rough surfaces such as painted walls and ceilings. They use a micromolding technique to make polymer fibers 28–57 micrometers wide, which they then dip into a liquid polymer to make tiny spatula-like tips. This increasing precision in design as compared to the actual gecko feet and ever-decreasing size of the polymer fibers that come from research and development are what make the adhesive forces stronger and more like those experienced by an actual gecko (Menon et al. 2004).

Snake-inspired robots are built by labs all over the world for the purpose of maneuvering around unpredictable obstacles in unstructured environments. Such environments range in size from as small and intricate as those within the human body, for which very small snake-bots are used in the medical industry, to the vast ocean floor, for which very large snake-bots are used. The engineering design tasks and considerations obviously vary greatly in these different environments. Generally, the cross-sectional diameter of all snake-bots is much smaller in size as compared to the entire length of the snake. This allows snakes, and snake-inspired robots, to maneuver through tight spaces. Paired with these anatomical dimensions, snake-bots use the periodic lateral undulation patterns described above. The fundamental method of design is to put together a chain of independent links with actuated joints that are moved by servo motors or similar devices which often comprise the links. This interconnection allows the individual links to move as dictated by the code that is written to control the actuating device. This allows the robot to change its shape to this periodic laterally undulating sinusoid. The simplicity of this design also allows snake-bots to achieve other necessary functions like wrapping around obstacles or grasping objects. Additionally, the chain configuration of links which are themselves modules is convenient because if one link in the

chain doesn't work the rest of the chain will still move as desired (Liljebäck et al. 2012; Ma 2001).

## Conclusion

In this chapter, we have provided only an overview of the truly impressive range of locomotor behaviors and specializations that have made the squamates so successful at survival even when they are introduced into new environments. We have seen how these types of movements are executed by the limbed and limbless members of Squamata and the many different types of gait transitions and sequences which have been observed in these lizards. This incredible range of locomotor behaviors, which can be utilized in all different kinds of environments, has also made them a subject of interest to engineers who design robots that need to play vital search and recovery roles in all kinds of environments. These environments can vary from environments as small and intricate as in the inside of the human body to those as large and unpredictable as the ocean floor. With such versatility and diversity of movements, it is clear that channeling such movements where applicable in the modern world is of great value to the scientific and engineering community.

<sup>3</sup>Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

## Introduction

Squamates are grouped within the paraphyletic “Reptilia,” with Testudines (turtles), Crocodylia (crocodiles, alligators, and gavials), and Rhynchocephalia (tuataras). Rhynchocephalia is the closest related to the Squamata, being its sister-group (clade Lepidosauria) and sharing many characters, as the skin covered by scales/plates that are partially impermeable and changed periodically, and a transversal cloacal slit. Squamata is the largest and most diversified clade of extant reptiles, comprising about 95% of its current diversity, with around 6500 lizard species, 3700 snake species, and 190 amphisbaenian species (Uetz and Hosek 2018).

It is not hard to recognize a squamate and morphologically distinguish it from other reptiles. The basic corporeal plan of a lizard, with an elevated head, short neck, four limbs, and long tail, distinguish them from most other reptiles (McDiarmid 2012). The differences between

Squamata and Rhynchocephalia are subtler – the main difference regards the presence of an ancestral skull in tuataras, with complete temporal bars defining the upper and lower temporal openings. Lizards lost the lower temporal bar, while snakes lost both (Kardong 2014). Many lizards and amphisbaenians, as well as all snakes, evolved the apodal elongated body, which is also distinct from other reptiles. Some important morphological features among snakes are the absence of eyelids and external ear, numerous vertebrae with modification on its connections, many paired internal organs elongated and some modified or lost (McDiarmid 2012). Moreover, all squamates have paired copulatory organs defined as hemipenis.

## External Morphology

Squamates are extremely diverse and can be quite specialized, not only with respect to their habitat or locomotion type, but also their morphology (Klein and Gorb 2014). Both snakes and amphisbaenians are legless elongated reptiles, even though a few snake species (blindsnakes and a few boas) exhibit rudimentary pelvic girdles that project externally as spurs, and a few amphisbaenians (*Bipes* spp.) exhibit reduced forelimbs. Additionally, there are different degrees of reduction in the number of limb elements to complete limblessness. The tail tends to be long and slender, but some snakes and lizards might exhibit bulbous or laterally expanded, or dorsoventrally or laterally compressed tails (Zug et al. 2001; Lillywhite 2014).

Several external morphological features associated to their sensory system include a parietal eye on the top of the head in a few lizards, distinct by the presence of a modified head scale, which is important for their photosensitivity. Additionally, a few snakes exhibit sense organs that respond and detect infrared radiation, very useful at night when visible light is usually unavailable. Such receptors are present as modified lip scales (= labial pits) in boas and as a facial pit (= loreal pits), located between the eye and the nostril, in pitvipers. Additionally, all snakes, amphisbaenians, and several

lizards present biphid tongues, which are extended to sweep air in front of them. The tongue collects airborne particles and is posteriorly retracts to perceive chemical signals, transferred to the vomeronasal organ located on the roof of the mouth. Tongues may also serve for prey capture, as in some chamaeleonids lizards (Kardong 2014).

The eyes of most squamates are large and conspicuous, especially in terrestrial and arboreal species. However, several fossorial species might present extremely reduced/degenerate eyes that can lie under the scales. Additionally, eyes of lizards exhibit bony plates (scleral ossicles) embedded in the sclera and surrounding the cornea (Zug et al. 2001). Pupils may vary from round to elliptical and are usually oriented vertically, even though it can be horizontally oriented in a few species. Extreme specializations in the squamate eye include the protrude lateral eyes of chameleons, with distinct anatomy of nodal and center points, in which the amplitude of movement is very large and the eyes move and focus independently (Zug et al. 2001; Lillywhite 2014).

Amphisbaenians exhibit the most conserved external morphology amongst Squamates, being characterized by their elongated bodies that are usually less than 150 mm long, with an extreme reduction (*Bipes* spp.) or complete loss of the limbs, and rudimentary/reduced eyes. Most of their distinctive features regard the dramatic modification of the head shapes, which is functionally correlated with specific tunneling behaviors. Heads may vary from (1) “shovel-headed,” with snouts dorsoventrally flattened with a strong craniofacial angle; (2) “keel-headed” forms; (3) “spade-headed” forms; or (4) “round-headed” forms – representing the most common form amongst amphisbaenians (Kearney 2003).

Within snakes, most small species belong to Scolecophidia, a group of fossorial snakes with reduced/absent eyes, rudimentary pelvic girdles that might be present as spurs, and a row of ventral scales that does not differ from those located dorsally in the trunk. Such snakes exhibit a relatively conserved external morphology, with variation occurring mostly in their head shape and scales pattern, dorsum colors and patterns, and presence/absence of a tail spine. The

*aesculapii*, (e) *Philodryas mato Grossoensis*, (f) *Philodryas argentea*. (Photos: Roberto Murta)

Alethinophidians comprise all the other snakes, with an extreme diversity in sizes, colors, scale patterns, and shape (Fig. 1).

Among squamates, lizards exhibit the highest level of morphological diversity (Fig. 2), varying from the ancestral type to forms that are completely legless. Many arboreal species are laterally compressed and may exhibit head and dorsum projections that provide an effective method for obscuring their surroundings. Several lizards are long with long tails, while others are short and robust with short tails. Some have strongly prehensile tails, used as fifth leg in climbing, others use their tails as whips to defend themselves, and many have laterally compressed tails used in swimming. Among lizards with limbs, there are species with four long/short limbs, as well as forms with only two (posterior) limbs. A few lizards have webbed feet and/or skin flaps that can be expanded and used as partial parachutes when jumping from arboreal perches. Some have adhesive pads on their toes, allowing them to climb vertical smooth surfaces; a few even have adhesive pads on the top of the tail, providing a fifth point of secure contact. Heads of lizards vary from flat and wide to long and thin. A wide variety of ornamentation exists as well, some for crypsis (camouflage) and some having to

do with social interactions. All lizards (except for a few gekkonids) have claws, which aid on locomotion on vertical surfaces (Pianka and Vitt 2003).

## Integument

Squamates in general exhibit a water-conserving integument (Withers and O'Shea 1993) with the skin modified into scales, which might be named as plates, tubercles, lamellae, etc., depending on the taxonomic group and location of the scales (Zug et al. 2001). Scales in various squamates have evolved in different sizes, geometries and gross structure, also varying regionally in the body, what is extremely relevant for systematics (Lillywhite 2014). The scales of a few lizards might be underlain by bony plates, called osteoderms. The integument of Amphisbaenians is characteristic in representing a disconnection to the trunk, enhancing its underground locomotion (Pough et al. 2018).

The epidermis of Squamata is composed by several keratin layers formed from cells of a basal layer, stratum germinativum, that is renewed together during shedding process (ecdysis). The most external cell layer, Oberhäutchen, presents

**Squamate Morphology, Fig. 2** Examples of diversity in lizards – (a) *Amphisbaena alba*, (b) *Polychrus acutirostris*, (c) *Notomabuya frenata*, (d) *Salvator*

three-dimensional microstructures on its surface (=microornamentation; Fig. 3), which are studied with Scanning Electron Microscopy. Since the first works about lizards and snakes microdermatoglyphics, these morphological patterns have been constantly suggested as an important taxonomic and systematic tools, and also to provide novel and interesting data on their biology.

## Internal Morphology

### Osteology

“Reptiles” exhibit diapsid skulls (Fig. 4), with two pairs of temporal fenestrae that are disconnected

by the superior temporal bar (formed by the squamosal and postorbital bones) and the inferior temporal bar (formed by jugal and quadradojugal bones). Among Lepidosauria, only the tuataras retained both fenestrae – squamates present exclusively the superior fenestra (lizards) or none (snakes) (Zug et al. 2001). The loss of the arch and fenestrae is associated to the increase of the flexibility (skull kinesis). The kinesis is derived from the presence of joints between many sections of the skull. A joint may occur in the posterior part of the skull (meta-kinetic joint), and between the dermic skull and braincase, at the parietal/supra-occipital suture (being the oldest kinetic articulation and, nowadays, occurring only in tuataras).

**Squamate Morphology, Fig. 3** Microornamentation of the dorsomedial scale of snakes on a 10 k zoom exhibiting the lamellate (a) and dotted (b) patterns. (Photos: Luciana O. Ramos)

**Squamate Morphology, Fig. 4** Scheme of a Dipasid skull based on tuatara

Two other joints evolved in braincase dermic bones – the dorsal meso-kinetic joint, present between frontals and parietal in many lizards and, in many snakes, a pro-kinetic joint, in the contact between nasals and prefrontals or frontals. The most impressive skull kinesis of Squamata is exclusive of snakes – streptostyly or quadrates rotation. Each quadrate is loosely connected to the dermatocranium and has the ventral extremity free. These lost ligaments allow the quadrate to rotate and swing back and forth and to the inside and outside (Zug et al. 2001).

The basic form of the squamate skull has the quadrate suspension with reduced dorsal and ventral processes of squamosal; loss of quadratojugal; fusion of the parietals; reduction of palatal dentition and anterior plate of the pterygoid; enclosure of the Vidian canal; shortening of the maxilla/dentary; among others (Evans 2008). Additionally, the snake skull seems to be pedomorphic in relation to lizards as claimed by several ontogenetic and anatomical studies. Considering the limbs, 15 synapomorphies are known for Squamata, and some of it are: elongate, gracile

limbs; specialized joints (ulna-ulnare and radius-radiale; first metacarpal-wrist; locked tibio-atragalar; ankle); intermedium reduced or absent; and second distal tarsal absent (Russel and Bauer 2008).

The “lizards” are divided into two major clades: Iguania and Scleroglossa which according to several studies includes the snake lineages. Iguanians show some primitive skull features (Fig. 5), as the retention of complete postorbital and upper temporal bars, retention of large upper temporal fenestrae and the absence of a hypokinetic joint. Still, their long period of independent evolution provided them with some specializations, such as frontals fused in the embryo, postfrontal reduced/absent, splenial absent/reduced, and teeth frequently tricuspid. Some Scleroglossa characters include prominent anterior descending processes of the frontals,

**Squamate Morphology, Fig. 5** Scheme of the dorsal/ventral views of a lizard skull (based on *Plica plica*). *Pm* = premaxilla, *Na* = nasal, *Mx* = maxilla, *Prf* = prefrontal, *L* = lacrimal, *J* = jugal, *Fr* = frontal, *Pa* = parietal, *Po* = postorbital, *Sq* = squamosal, *Vo* = vomer, *Pt* = pterygoid, *De* = dentary, *Ar* = articular, *Bo* = basioccipital

loss of dorsal process of squamosal, vomers reduced in length, and septomaxillae dorsally expanded and convex (Evans 2008).

The morphological diversity of the lizards' axial skeleton reflects the wide extent of their morphological specializations, as previously shown. The number of presacral vertebrae varies from 16 in some Chamaleonidae to as much as 116 in some Dibamidae. The Sauria (lizards) shows two main morphological types of vertebrae, those with an amphicoelous centrum and those with a procoelous centrum. Sauria (=lizards) ribs are usually called holocephalous (one of the two articulations between the rib and the vertebra has disappeared), but the first cervical ribs of *Varanus* may still be dichiocephalous. On the following vertebrae, and generally in the cervical and anterior trunk of lizards, the two articulations fuse to form a single synapophysis, but the latter remains oblong, keeping a vestige of dichiocephaly. In the posterior part of the trunk, the single articular facet becomes hemispherical and the ribs clearly holocephalous. The vertebral column is divided into cervical, trunk, sacral/cloacal, and caudal regions (Hoffstetter and Gasc 1969).

The amphisbaenians are highly specialized lizards that have a completely different morphology and effect penetration of the substratum by movements of their head. Compared to other lizards, the amphisbaenians skull (Fig. 6) has the following peculiarities: absence of palatal and suborbital fenestrae; lateral parietal downgrowths enclosing the braincase; fusion of bones in the occipital segment and mandible; presence of secondary palate; absence of major mobile articulations; presence of a tabulosphenoid and of a paired elements-X (without clear homology to any other lizard bone), among others. Most of the bones overlap to avoid slippage when the large pressures associated with excavation are applied to the head. Their skull can be divided into five morpho-functional units: an occipital segment, intermediate segment, snout, palatal series, and mandibulae (Gans and Montero 2008).

In amphisbaenians, the number of precloacal vertebrae varies from 64 to 145. Each vertebra is generally depressed with transversely widened

**Squamate Morphology, Fig. 6** Scheme of the dorsal/ventral views of an amphisbaenian skull (based on *Amphisbaena fuliginosa*). Pm = premaxilla, Na = nasal, Mx = maxilla, Fr = frontal, Pa = parietal, Pf = prefrontal, Pl = palatine, Qd = quadrate, Oc = occipital complex, De = dentary, An = angular, Cb = compound bone, E-x = element-X, Pbs = parabasisphenoid

condyle, and flat ventral face of the centrum with parallel lateral borders. Neural spines are lacking in the trunk region, and prezygapophysial processes are more or less clearly present. The division of the column into regions is difficult. There is generally a vestigial pectoral girdle with no connections with the ribs, and a pelvic girdle, also without connection with vertebral column – thus, there is no differentiated sacrum. A series of vertebrae that bear forked ribs may be identified as cloacals. The caudal region is always short, comprising fewer than 30 vertebrae (Hoffstetter and Gasc 1969). Among amphisbaenians, only one family/genus presents limbs (Bipedidae, *Bipes*), and it is restricted to the forelimbs.

In snakes' skull, the frontals and parietal have expanded ventrally around the sides of the skull, forming the major part of the braincase wall. Its enlargement resulted in the loss of many other dermic bones. Skull characters are so important to snakes that the taxon is diagnosed based in some features, as the absence of the lacrimal, squamosal, and epipterygoid bones (Estes et al. 1988) and the absence of bony mandibular

symphysis and contact between frontal and maxilla bones (Conrad 2008) (Fig. 7).

“Scoleophidians” snakes present several exclusive skull features, especially in braincase and snout. The snout forms a bulbous terminus to the end of the skull and is attached to the braincase by peripheral sutures rather than by a central strut (Cundall and Irish 2008). The skull of such species has been interpreted as an adaptation to its burrowing and feeding habits (scoleophidians feed primarily on small arthropods). Such snakes have a shortened lower jaw and suspensorial elements that are angled anteroventrally, rather than vertically or posteroventrally, palatines and pterygoid without teeth, supratemporal lost, mandible shorter than combine length of braincase and snout, among other features (Fig. 8) (Cundall and Irish 2008). Alethinophidians, unlike scoleophidians, present medial pillars on the frontal bones, a laterosphenoid bone in the middle of the trigeminal foramen, and a toothed anterior process on the palatine. None of these features is uniformly present among the group though. All the species present a lower jaw as long as or longer than the skull and a snout both prokinetic and rhinokinetic. The most conspicuous consequence of such differences among Scoleophidians and Alethinophidians is the enlargement of the gape size in the latter (Cundall and Irish 2008). According to the dentition, such snakes are divided into four categories: aglyphous – does not possess specialized teeth to venom injection; opisthoglyphous – a pair of grooved teeth (fangs) located in the bottom of the maxilla; proteroglyphous – a pair of grooved teeth (fangs), located in the anterior portion of the maxilla; and solenoglyphous – a pair of large and movable teeth (fangs), with a canal by which the venom is inoculated, located in the anterior portion of maxilla.

The absence of pectoral girdle hampers the definition of the boundary between the cervical and trunk regions. As in amphisbaenians, the site of the cloaca and associated organs is reflected in the vertebral morphology. The vertebral number is always high, varying from 160 to more than 400 (precloacal ranging from 120 to over 320). There are no fundamental differences between the vertebral morphology of snakes and the other

squamates, but there are a certain number of typically ophidian characters. The centrum bears a large anterior cotyle (glenoid cavity) faced ventrally, and a dorsally turned posterior condyle, which widely overlaps the transverse section of the centrum. The ventral surface of the centrum is limited on both sides by a more or less clear crest (which are completely lacking in some families). The hypapophyses arise from the posterior part of the centrum in the mid-ventral line. In the middle and posterior parts of

the trunk, the hypapophyses may be reduced to a simple haemal keel, disappearing completely in some burrowing families. In the caudal region, they are replaced, when present, by paired haemapophyses which fuse to the centrum. The neural arch consists of a roof and walls. The neural crest is often trilobate in section. The ribs are completely ossified and generally robust with a double articular facet – each part articulated with one of the two areas of the synapophyses (Hoffstetter and Gasc 1969).

## Myology

Squamates, as well as other amniotes, exhibit two major sets of muscles: the cranial (jaw and pharyngeal musculature and extrinsic eye muscles) and postcranial muscles (appendicular and axial) (Kardong 2014). The loss of the temporal arches in the skull, as well as the great differences in the degree of cranial kineticism, is directly reflected in the wide variation of the squamate cranial muscles. Differences in the position and configuration of the upper temporal arch and the relative width of the dorsal temporal fossa might have caused radical changes in the arrangement of the external and internal adductor muscles. Several fossorial squamates exhibit vestigial or absent extrinsic eye muscles that are possibly directly associated to the reduced eyes (Haas 1973). The muscles of the head of snakes differ strikingly and in many ways from those of lizards and are somehow closely and similar to amphisbaenians. However, the latter has developed an extremely strong biting apparatus, while in the microphagous snakes, cranial kinesis and horizontal movements of the jaws are more important. The process to swallow preys in ophidians is aided by the complex *constrictor internus dorsalis* group of muscles, which effect the protraction and retraction of the bony palate, and the complicated and diversified concomitant movement of the maxillae and bones of the snout (Haas 1973).

In Squamate (as well as in other amniotes), the horizontal septum that splits the epaxial and hipaxial muscles is lost or indistinct, although the supply by the dorsal and ventral rami of the spinal nerve still aids on the identification of such muscles. In lizards (except legless ones), even though lateral undulations of the vertebral column contribute to locomotion, limbs become more important in providing propulsive forces. Therefore, the epaxial muscles associated to vertebral column are reduced, and the musculature associated to the appendices are much more conspicuous. In snakes, amphisbaenians, and limbless lizards, the axial muscles are very important on providing propulsive forces and, therefore, are prominently developed. The hypaxial muscles form much of the body wall and are associated to breathing as it is attached to the rib cage. Most

epaxial and hipaxial muscles in squamates split into several layers forming many differentiate muscles that span several segments (Kardong 2014).

## Visceral Morphology

Lungs represent the main respiratory surface of squamates, although some degree of cutaneous respiration might be found in several species (Zug et al. 2001; Kardong 2014). The lungs of snakes and most lizards typically include a single central air chamber into which faveoli open (Kardong 2014). Thoracic aspiration is used to ventilate the lungs, and, in lizards, intercostal muscles between the ribs contract and force the ribs forward and outward (Zug et al. 2001). In several snakes, the faveoli may be reduced in the posterior part of the lung, leaving it as a nonexchange region, traditionally named as air sacs or saccular lungs. In monitor lizards, the single central air chamber is subdivided into numerous internal chambers that receive air from the trachea.

The elongated body plan leads to several rearrangements in the organ topography in snakes, amphisbaenids, and elongated-legless lizards. Among the snake organs, the respiratory system exhibits the highest level of specialization of squamates. In primitive snakes, the lungs are paired, but in many advanced snakes the left lung is reduced and often entirely lost (Kardong 2014). A few snakes (scolecophidians and some advanced snakes) exhibit a tracheal lung, which is characterized by the presence of a vascular portion of the lung located anterior to the heart (Wallach 1998).

Squamates show a typical double circulation, which includes a three chambered heart, with the retention of the aortic arches III, IV, and VI. The ventral aorta is subdivided forming the left and right aortic arches and the pulmonary trunk. Such configuration in the aortic arches provides one pulmonary circuit and two systemic circuits, each of which arising independently from the heart. Although the ventricle is given as a single and undivided cavity, three interconnected compartments are present and separated from each other by a muscular ridge. Thus, a few authors might assign the squamate heart as

five-chambered, composed of two atria and three compartments of the ventricle, or six chambers if the sinus venosus is counted (Kardong 2014).

Two types of tooth implantation are present in squamates: acrodonty (a few lizards) and pleurodonty (lizards, snakes and amphisbaenids). Additional features of the squamates digestive system include a buccal cavity lacking a secondary palate and several oral glands that support food digestion. In both snakes and lizards, such head glands have evolved independently several times to venom glands that support not only food ingestion, but prey capture. The alimentary canal is very diverse in size and regionalization, mostly depending on type of food ingested. However, its general pattern consists on a short esophagus, with gradual transition to stomach, which is followed by the small and large intestines that finally open in the cloaca. The cloaca is partially differentiated into the coprodeum, a chamber into which the large intestine empties, and the urodeum, into which the urogenital system empties. The alimentary tract of herbivores, particularly the large intestine, is consistently longer and more voluminous than that of similar sized carnivores (O'Grady et al. 2005). In some herbivorous lizards, a cecum is present between the small and large intestines (Kardong 2014). The body elongation on snakes resulted on an elongate digestive system, with inconspicuous folds in the small intestine.

Squamates exhibit a series of oral glands: supralabial and infralabial glands are present

along the upper and lower lips; lingual and sublingual glands; premaxillary and nasal glands, in association with the snout; and palatine gland, along the roof of the mouth (Fig. 9). These glands release mucus to lubricate the prey during intraoral and esophageal transport. The lacrimal and Harderian glands release secretions that bathe the eye and vomeronasal organ. Duvernoy's gland, situated along the posterior upper lip, is found in many nonvenomous snakes and releases its serous secretion via a duct adjacent to the posterior maxillary teeth. In venomous snakes, the venom gland, homologue of Duvernoy's gland, secretes a cocktail of different chemicals with various functions – some toxic, some digestive (Kardong 2014). While venom and Duvernoy's glands are always located in the upper jaw, transferring the venom through maxillary teeth, lizards venom glands are usually located in the lower jaw and transferred through both maxillary and mandibular teeth (Fry et al. 2006).

All squamates bear metanephric kidneys, with primary uricotelism as their nitrogen waste. However, nephron structure can be quite different from one taxonomic group to the next and may appear at first to have no obvious correlation with the phylogenetic position, but most likely to their environmental demand. The kidney typically lacks the distinct color and functional distinction of the mammalian cortex and medulla. The kidneys are paired, lobular (weakly so in some lizards), elliptical, pink or red structures that are

**Squamate Morphology, Fig. 9** Illustration of the head glands of *Atractus potschi* in lateral view. Na = Nasal glands, Ha = Harderian gland, Su = Supralabial gland, In = Infralabial gland, lao = *Musculus levator anguli oris*,

aes = *Musculus adductor mandibulae externus superficialis*, aem = *Musculus adductor mandibulae externus medialis*

located retroperitoneally (extracoelomically). Kidneys are posterior to the level of the ilial crest in most lizards and usually lack distinct lobes. Snake kidneys are distinctly lobed and elongated, found in the posterior third of the bodies, with the right kidney occurring anterior (approximately 69–77% of snout-vent length [SVL]) to the left kidney (~74–82% of SVL). Snakes lack urinary bladders; nitrogenous wastes are refluxed from the cloaca into the rectum, where uric acid is stored and further ion reclamation may occur. Several species of lizard lack urinary bladders or develop just a vestigial bladder, including some varanids, agamids and a few gekkonids (Wyneken 2013).

The gonads (ovaries and testes) are located dorsally in the body cavity, posterior to the lungs (except in elongated individuals, where lungs might overcome the right ovary), and ventral to the kidneys and peritoneal wall. The female reproductive tract is composed of paired ovaries, and oviducts (that might be missing in a few snake species) supported by mesenteries. In lizards, at least the caudal part of each ovary is attached to the peritoneum along the ventromedial surface of each kidney. In some lizards with highly modified lungs, such as chameleons, the ovary may extend cranial between the two lungs. In snakes the ovaries tend to be well posterior to the lung(s) and saccular lung and anterior to the kidneys, attached

to the dorsal body wall by the mesovarium, while the testes can be round or fusiform in shape (Mader and Wyneken 2002).

## Hemipenis

Unlike other reptiles, Squamata have a pair of hemipenis, an intromittent copulatory organ that originates at the junction of the cloacal vent and the base of the tail. Although squamates exhibit two hemipenis, during copulation, only one of them is inserted in the cloaca of the female (Kardong 2014). Each hemipenis is usually grooved (*sulcus spermaticus*) to allow sperm transport. A retractor muscle returns each hemipenis to the body, a process called invagination, storing the organ at a pocket located at the base of the tail, posterior to the vent. During erection, muscle action and hemotumescence force each hemipenis through the cloaca, expanding it out through the vent, as a process named evagination (Kardong 2014).

The hemipenial morphology is widely used in squamates taxonomy and systematics. Hemipenis may be uni- or bilobed and can bear many different ornaments, such as large spines, spicules, body calyces, lobular crest or ridge, calycular pockets, capitular groove, and capitular calyces (Zaher 1999) (Fig. 10).

## Squamate Sensory Systems

Ryan K. Schott  
Department of Ecology and Evolutionary  
Biology, University of Toronto,  
Toronto, ON, Canada

Squamates (lizards and snakes) are one of the most diverse groups of vertebrates with over 10,000 species currently recognized (Utey et al. 2017). They have a near worldwide distribution and occupy most ecological niches and lifestyles with terrestrial, aquatic, fossorial, and arboreal species. Squamates utilize the typical vertebrate sensory systems to varying degrees, including the visual, chemosensory, auditory, vestibular, and somatosensory systems, and are the only group known to have developed an image-forming infrared system. It is through sensory systems that squamates, and other animals, are able to detect and respond to both their internal and external environments, and as such sensory systems govern all aspects of squamate behavior. In this section, the morphology, function, and behavioral implications of each major squamate sensory system are described, with a focus on how they differ from other vertebrates.

### Visual System

Vision is perhaps the best understood and most studied of the sensory systems, and this reflects its importance to most, but not all, animals. Squamates utilize vision for nearly all aspects of their behavior, albeit to differing degrees. This includes prey localization and capture, predator avoidance, identification of conspecifics and mating, and circadian rhythm. Vision often works in concert with other sensory systems, and in some cases, visual cues alone are insufficient to elicit a behavioral

response, such as with prey capture or mating where chemical cues may also be needed. While most squamates have well-developed visual systems, some highly fossorial groups, such as amphisbaenians and scolecophidian snakes, have highly reduced visual systems and may lack fully developed eyes.

Vision is mediated by the eye, which in squamates resembles the typical vertebrate camera-style eye (Walls 1942). This consists of the cornea, iris, ciliary body, pupil, lens, retina, retinal pigment epithelium, choroid, and sclera. In squamates and some other reptiles, the sclera contains additional bony and cartilaginous elements, the scleral ossicles and cartilage, which form a ring around the cornea. These provide additional support during accommodation, which in most squamates occurs through compression of the lens by the ciliary muscles to make it more spherical. In many squamates, including all snakes and most geckos, the eyelids have fused and become transparent, forming a protective covering over the eye called the spectacle. Squamates possess another additional structure, the conus papillaris, believed to be homologous to the pecten oculi in birds, which provides additional nutrients to the retina. The eyes of snakes, however, differ significantly from those of other squamates and reptiles. The modifications include changes to the shape of the eye and lens to become more spherical and rigid, loss of scleral cartilage and ossicles, loss of ciliary muscles, and development of a new method of accommodation through movement of the lens forward toward the cornea, rather than constriction of the lens. These differences have been argued to be related to either the fossorial or the aquatic origins of snakes, and there is ongoing debate on this topic.

The size and position of the eyes and the shape of the pupil in squamates can vary considerably with the ecologies of different species. The eyes are typically located on the side of the head resulting in little binocular overlap. This is particularly true of most lizards, which have some of the strongest laterality of the eyes, although monitors (Varanidae) are one of the exceptions and have larger binocular overlap. Chameleons are unique in having turreted eyes that can be rotated

independently 180° horizontally and more than 90° vertically (Sandor et al. 2001). When both eyes are pointed forward, such as when fixating on prey, there is a large degree of binocular overlap. Snakes typically have higher degrees of binocular overlap, especially in species that are visual predators. The most extreme example of this is in the tree snake *Ahaetulla* which has a keyhole pupil and a groove on the side of the head that serve to further increase the binocular overlap, but without sacrificing lateral vision (Walls 1942). Most diurnal squamates have round pupils, although the horizontal and keyhole pupils of some arboreal snakes as mentioned above are an exception. Slit pupils are common in nocturnal and crepuscular species and were found to be associated with multifocal lenses that may reduce chromatic aberration caused by relatively large pupils that are necessary to increase sensitivity (Malmstrom and Kroger 2006). It has also been suggested that pupil shape is correlated with foraging mode, with slit pupils found most often in ambush predators that are active both day and night (Banks et al. 2015).

The squamate retina, typical of vertebrates generally, is a thin multilayered neural tissue. It contains the light-sensitive photoreceptors and is also the location of the first step of visual processing before the signal is sent to the higher visual centers of the brain for further processing. The photoreceptors are the cells responsible for the absorption of light and the subsequent visual transduction cascade, which produces the electrical signal that ultimately results in vision. Squamates, like other vertebrates, have two kinds of photoreceptor cells often identified based on their outer segment morphology: rods for vision in dim light and cones for vision in bright light and, in some cases, color vision. For this reason, most vertebrates have duplex retinas containing both rods and cones; squamates however are unique in that many species have simplex retinas that contain only morphological cones or morphological rods. The inferred transitions between rod and cones are termed photoreceptor transmutations (see below).

Visual pigments are molecules contained in the photoreceptor outer segments that initiate the first

step in vision through the absorption of a photon. They are composed of an opsin protein covalently bound to a light-absorbing chromophore (retinal). Different visual pigments absorb light maximally at different wavelengths due to differences in the opsin protein and/or chromophore (A1 vs. A2), and these differences provide the basis for color vision. Adjustment of the wavelength of maximal absorbance ( $\lambda_{\text{max}}$ ) is one of the ways that squamates and other vertebrates can adapt their visual system to different spectral environments. Ancestrally squamates have maintained the full complement of vertebrate visual opsins – a single rod opsin (RH1) and four cone opsins (LWS, RH2, SWS2, SWS1) – and thus have a wide range of spectral sensitivity from the UV to the far red. Some groups, however, have lost opsins, such as snakes, which lost the RH2 and SWS2 opsins, and geckos, which lost the RH1 and SWS2 opsins. Most squamates utilize only the A1 chromophore, but the Carolina anole may be unique among terrestrial vertebrates in utilizing exclusively A2, which results in highly red-shifted visual pigments (Loew et al. 2002).

Some of the most striking aspects of squamate visual systems is the preponderance of simplex retinas and the large amount of variation in the morphology of the photoreceptor cells. Diurnal lizards and diurnal caenophidian snakes typically have morphologically all-cone retinas, while some nocturnal lizards and nocturnal caenophidian snakes can have morphologically all-rod retinas. Other species have photoreceptors with morphologies intermediate between rods and cones. The implied transitions between all-cone and all-rod retinas led Walls (1942) to formulate his photoreceptor transmutation hypothesis. Photoreceptor transmutation is the evolutionary process by which a cone can be converted into a rod or vice versa.

The best example of photoreceptor transmutation occurs in geckos. Most geckos are nocturnal and have retinas that contain only rod-like photoreceptors. Walls (1942) proposed that the all-rod retinas of nocturnal geckos were derived from the all-cone retinas of ancestral diurnal lizards. Furthermore, he hypothesized that extant diurnal geckos reverted to diurnality, and consequently

their all-rod retinas were transmuted back to all-cone retinas. Support for this hypothesis has come from several avenues of research. Röhl (2000) found that nocturnal gecko “rods” were actually cones at all levels of their ultrastructure, having such cone features as open outer segment membranes. Furthermore, the “rods” were found to use only cone opsins and other cone phototransduction machinery, not the phototransduction machinery that is specific to normal rod photoreceptors (Zhang et al. 2006). The rod-like cones of geckos, however, function more similarly to rods (Zhang et al. 2006). Together these studies provide strong support for the hypothesis that gecko “rods” were “transmuted” from diurnal lizard cones. With their transmuted “all-rod” retinas, nocturnal geckos have been found to be able to discriminate colors at low light levels where humans are color blind (Roth and Kelber 2004).

Snakes are the second group of squamates in which photoreceptor transmutation appears to be important. Non-caenophidian snakes have retinas containing only reduced rods (scoleophidians) or simple duplex retinas with single cones and rods (“henophidian”-grade species, such as pythons and boas); however, caenophidian snakes have retinas that are more complex and variable, with multiple photoreceptor transmutation events inferred between taxa with simplex retinas (Walls 1942). Recently, the first molecular evidence for photoreceptor transmutation in snakes was uncovered. The diurnal garter snake, which has a morphologically all-cone retina, expresses RH1 (the rod visual pigment) in a cone-like photoreceptor that is actually evolutionarily derived from a rod, based on its ultrastructure and rod-specific molecular components (Schott et al. 2016). The transmuted cone-like rods may contribute to an increased range of spectral sensitivity and provide the basis for trichromatic color vision under mesopic (when both the rods and cones are typically active) and, potentially even photopic, conditions. The role of all-rod retinas in nocturnal caenophidian snakes has not been studied, but similarly to geckos, these “rods” may contribute to nocturnal color vision.

## Chemosensory Systems

Squamates rely heavily on chemosensory systems to direct a large number of behaviors including prey detection and acquisition, predator avoidance, mating, aggregation, and other conspecific interactions and habitat selection. Squamates have three chemical senses: olfaction, vomeronasal olfaction, and gustation (taste), each of which utilizes distinct organs and has specialized functions. The reliance on, and specific uses of, particular systems varies between different squamate groups. The olfactory system is generally thought to be useful for long-range detection of broad chemical signals, which can then trigger the shorter range, but more discriminatory, vomeronasal system. This proposed functional link between the olfactory and vomeronasal system is known as the Cowles and Phelan (1958) hypothesis. While support for this hypothesis has been found in snakes (Halpern et al. 1997), its general applicability to squamates has not been tested despite its general acceptance (Schwenk 1993). The gustation system is poorly studied in squamates, but is generally thought to be useful for discrimination of prey items prior to ingestion, although other roles cannot be ruled out. Each of the three chemosensory systems is described below.

### Olfactory System

The olfactory system serves to detect volatile chemicals (odorants) in the air through the paired main olfactory organs. In squamates, these organs follow the typical vertebrate pattern (for details see Halpern 1992). The olfactory (or odorant) receptors (ORs) are the proteins expressed in the olfactory sensory neurons that detect and respond to odorants (Malnic et al. 2010). ORs are GPCRs, similar to the opsin proteins described above, and comprise one of the largest protein families with over 1000 known genes in some mammals. ORs typically respond to multiple odorants, and it is the combination of ORs activated that encodes specific smells. Once activated, ORs activate a G-protein transduction pathway to convert the chemical signal onto an electric one. The number of olfactory genes is generally viewed as

correlating with olfactory ability (e.g., mice have ~1000 ORs, while humans have ~350), although other aspects, such as the surface area of the olfactory epithelia, may be equally or more important (Malnic et al. 2010). The number of ORs in squamates has not been well studied, but recent analyses have shown that snakes possess 350–480 intact (i.e., putatively functional) ORs, while the lizard *Anolis* possesses ~100, and the gecko *Gekko* possesses ~250 (Vandeweghe et al. 2016; Yin et al. 2016). In comparison crocodilians have ~450–600 ORs and turtles ~800–1000 (Vandeweghe et al. 2016), suggesting that the OR repertoires of squamates may be smaller than other reptiles. The larger number of ORs found in snakes, relative to other squamates, might suggest a larger importance of olfaction, at least in some species; however, due to the relatively small number of squamates analyzed and the difficulty of accurately determining OR numbers, these differences should be considered with caution.

Specific uses of the olfactory system in squamates have been largely overlooked due to the predominant view, based on the Cowles and Phelan (1958) hypothesis, that the olfactory system serves primarily as an early (i.e., long range) detection system that triggers the more discriminatory vomeronasal system. This view may be accurate for snakes, which are often viewed as vomeronasal specialists, but other squamates may rely more heavily on olfaction (Schwenk 1993). For example, geckos have relatively large main olfactory bulbs (compared to overall brain size and accessory olfactory bulb size) suggesting a strong investment in olfaction. Furthermore, olfactory cues have been found to be sufficient to trigger antipredator behaviors and detection of prey items in the absence of tongue-flicking that is associated with the vomeronasal system.

### Vomeronasal System

The vomeronasal system is distinct from the main olfactory system and, in most vertebrates, is viewed as an accessory system. Squamates are the exception to this, and many, especially snakes, could be considered vomeronasal specialists. While the vomeronasal and main olfactory systems are distinct, there may be some overlap in the

chemicals they detect as both can respond to volatile, airborne odorants and pheromones. The vomeronasal system is also sensitive to nonvolatile, high molecular weight compounds, which the main olfactory system is not able to detect.

The vomeronasal system is mediated by the paired vomeronasal organs (VNOs, also known as Jacobson's organ). The VNOs typically form as part of the nasal cavity, but uniquely in squamates become fully isolated (Schwenk 1995). In squamates, the VNOs are located at the base of the nasal cavity just above the palate. The roof of each spherical VNOs is covered with the vomeronasal sensory epithelium, which projects to the accessory olfactory lobe through the accessory olfactory (vomeronasal) nerve. The VNO communicates with the oral cavity through paired openings in the palate, the vomeronasal fenestrae. Stimulation of the vomeronasal system, unlike the olfactory system, requires active delivery of chemicals to the vomeronasal sensory epithelium by the tongue (Filoramo and Schwenk 2009). To facilitate this, squamates have evolved a derived tongue-flicking behavior used to sample chemicals from the air or from surfaces, which can then be delivered to the VNOs through the vomeronasal fenestrae.

Squamates generally all utilize tongue-flicking to some degree, although some groups, such as geckos and chameleons, only use tongue-flicking to sample surfaces and not the air, which may reflect an increased reliance on olfaction and vision, respectively. Squamates that also use tongue-flicking to sample the air tend to have additional specializations including oscillatory tongue-flicks and forked tongues. Oscillatory tongue-flicks appear to be an adaptation for collecting airborne odorants (Daghfous et al. 2012), while forked tongues can act as chemosensory edge detectors and allow snakes and other squamates with forked tongues to effectively follow odor (i.e., pheromone) trails of prey and conspecifics (Schwenk 1995). In many species, as discussed above, olfactory cues may trigger tongue-flicking toward the air activating the vomeronasal system to allow more precise localization of a chemical signal. Substrate aimed tongue-flicking may then allow discrimination

of nonvolatile, high molecular compounds providing additional information on the source of the signal including species identity, sex, and reproductive status, enabling the behaviors mediated by the squamate chemosensory system mentioned at the beginning of this section. Additional details on the functions and behaviors associated with the vomeronasal system are reviewed by Halpern (1992).

Similar to the olfactory system, the vomeronasal system is mediated by a G-protein-coupled receptor pathway. There are two types of vomeronasal receptors, V1R and V2R, which are thought to mainly recognize small airborne molecules and water-soluble molecules, respectively. This is thought to be reflected by the high V1R complements found in terrestrial mammals and the high V2R in aquatic amphibians, but squamates prove an exception to this pattern (Silva and Antunes 2017). The high number of V2R genes in squamates could be linked to substrate sampling of nonvolatile compounds through tongue-flicking, although this has not been tested. Overall, very little is known about the specificity of V1R and V2R, and considerably more work is needed to understand the evolution and function of these proteins in squamates.

### Gustatory System

Gustation is the perception of taste, which is mediated by taste buds that, in squamates, are variably present on the tongue and surface of the oral cavity. Many species have taste buds concentrated on the tip of the tongue, although others, such as snakes, have only palatal taste buds. A few species lack taste buds altogether (e.g., monitor lizards). The gustatory system is by far the least studied of the three chemosensory systems, but its primary function in squamates appears to be limited to discrimination of prey items prior to ingestion. Several species have been shown to discriminate between prey items, and some, including both lizards and snakes, may be capable of learned aversion to food following illness (see Schwenk 2008 and references therein).

Some of the genes encoding taste receptors in vertebrates have been uncovered. These include the taste receptors for four of the five main tastes:

sweet (T1R), umami (T1R), bitter (T2R), and salty (ENaC). The receptors for sour taste and those for other “tastes” that the gustatory system can detect (at least in some vertebrates), such as water, fat, and complex carbohydrates, are unclear (Bachmanov et al. 2014). Little is known about the distribution and function of these genes in squamates. Recently the repertoire of bitter taste receptors was analyzed in two lizards (*Anolis* and *Gekko*) and several snakes. It was found that the lizards underwent a considerable expansion of bitter taste receptors relative to other reptiles with 36 and 50 genes in *Anolis* and *Gekko*, respectively, compared to 2–10 in crocodilians and turtles (Zhong et al. 2017). Snakes were found to have lost genes retaining only one or two genes or, in the case of the garter snake, no genes. The expansion of bitter taste receptor genes in lizards may be related to the increased exposure to toxins that accompanies an insectivorous diet (Zhong et al. 2017), but this hypothesis requires further testing, as does the function of gustatory genes in squamates more generally.

### Auditory and Vestibular Systems

In squamates the auditory and vestibular systems are mediated by the ears and function in hearing and balance, respectively. In squamates there is no outer ear in the mammalian sense, although there may be a slight depression and reduction of the scales around the ear opening and a short passage (external auditory meatus) connecting to the middle ear (Baird 1970). The middle ear is variable in squamates, but consists of the structures that transfer vibrations to the inner ear. This typically includes a tympanic membrane (eardrum), but in some species, especially fossorial and semi-fossorial forms, it has been lost. The auditory (Eustachian) tube is short and broad. The stapes has a footplate laterally, where it connects to the inner ear through the oval window, and a long, slender shaft medially. The extrastapes, a cartilaginous element, extends from the stapes medially to the tympanic membrane with several distinct processes that travel across the tympanic membrane providing stability and acting as a lever effect that

enhances the transmission of sound pressure. The extrastapes may also be connected to the quadrate, which can pick up vibrations and transmit them to the stapes. Snakes are notable in the lack of not only the tympanic membrane but also the tympanic cavity and the auditory tube. Despite this, snakes are not deaf, as is often supposed, and can still hear low-frequency airborne sounds, as well as ground vibrations (Young et al. 2014).

The inner ear follows the general vertebrate pattern. The cochlear duct contains the auditory sensory epithelium, called the basilar papilla. It is composed of sensory hair cells that are receptive to movement in their surrounding perilymphatic fluid caused by motion of the stapedial footplate. Similarly, the macula in the saccule and utricle, and the crista ampullaris in the ampulae of the semicircular canals, contain the sensory hair cells of the vestibular system. The macula detects linear acceleration and gravity, while the semicircular canal detects rotational movement. For additional details on the anatomy and function of the ear, see Baird (1970).

The auditory system of squamates functions in a variety of contexts, but not all have been well studied. Uses employed by various groups include prey capture, intraspecific communication, and predator avoidance (Young et al. 2014). The wide auditory tube in lizards makes the ear well suited to localization of prey due to acoustic coupling, which can vastly improve directionality of sound detection. Several species have been found to use auditory cues to locate insects. Remarkably, sand vipers have been shown to be able to locate and capture prey using only ground-borne vibrations. The viper rests its head on the sand where surface waves produced by potential prey cause vibrations in the two independent sides of the lower jaw, which are relayed (on each side) through the quadrate and stapes to the inner ear. Intraspecific communication in squamates is perhaps best developed in geckos, but may also be present in other groups. Geckos in particular are known for producing complex calls that have been implicated in territory defense, male-male competition, and mate attraction. Most squamates, including snakes, will respond to auditory cues produced by predators, but specific research

in this area is lacking. For additional details on uses of the auditory system, see Young et al. (2014) and references therein.

The vestibular system functions in balance and orientation, which is generally important for locomotion. Most research on functional differences in the vestibular system have focused on the morphology of the semicircular canals. In squamates, inner ear morphology is highly variable, but has been shown to correlate with different ecologies, although there is substantial overlap and a strong phylogenetic signal (Palci et al. 2017).

## Somatosensory System

Somatosensory systems mediate interactions with both the external and internal environments providing the senses of touch, pressure, pain (nociception), temperature, balance, and body position (proprioception). These senses each have particular receptors including mechanoreceptors (for touch and pressure) and nociceptors (for pain). Squamates, as in most vertebrates, have cutaneous sensory organs in a variety of forms across the body. These contain mechanoreceptors (scale sensilla), nociceptors, and temperature receptors. Internally, proprioceptor organs are specialized mechanoreceptors found in the muscles, tendons, and joints. These organs detect changes in muscle length and tension and joint position, allowing the coordinated movement of the limbs and body. For a detailed review, see von Düring and Miller (1979).

A remarkable mechanosensory specialization occurs in the tentacled snake (*Erpeton tentaculatus*). This snake species is fully aquatic and is a specialized fish hunter. Tentacled snakes use a sit-and-wait hunting strategy where they adopt a J-shaped posture. When the fish enters the concave area of the J, the snake strikes at the predicted future position of the fish (Catania et al. 2010). Tentacled snakes are highly visual and were found to be able to track and strike prey based on visual cues alone. However, tentacled snakes were still able to strike at and capture prey in complete darkness, although with reduced frequency (Catania et al. 2010). This is accomplished

using their namesake paired tentacles. These tentacles are highly sensitive mechanosensors able to detect water movements produced by fish. They are innervated by branches of the ophthalmic and maxillary nerves, and visual and mechanosensory cues may be integrated in the optic tectum to enhance localization of prey.

## Infrared System

Most animals can sense changes in temperature, but very few can actually “see” infrared thermal radiation. Three groups of snakes, the pythons (Pythonidae), boas (Boidae), and pit vipers (Crotalinae) have specialized infrared receptors to do just that. These snakes are able to sense, locate, and strike warm-blooded prey in the absence of other sensory information (e.g., visual or olfactory cues; Goris 2011). While prey detection is typically thought to be the main use of the infrared sense, it is actually a more general use sensory system that integrates with and supplements the visual system. Other specific uses include predator detection, behavioral thermoregulation, and den site selection (Krochmal et al. 2004).

In most infrared-sensitive snakes, the receptors are contained within specialized pit organs; however, in some boas (e.g., *Boa constrictor*), the receptors are simply located on the proximal and distal edges of labial scales (Goris 2011). In other boas, the receptors are located in the same area, but pits are formed between the two receptor-bearing scales. In pythons the pits are formed from a depression within a labial scale with the receptors located at the base of the pit (i.e., the pit fundus). Thus, the receptor layer at the base functions as a retina, and the overhanging mouth of the pit acts as the aperture of a pinhole camera.

The pit organs of pit vipers are located in the loreal region between the eye and nostril and are more complex than that of pythons and boas. They consist of a narrow opening into an inner and outer chamber separated by a suspended receptor-bearing membrane. While the inner chamber is blocked off from the main opening, it is connected to the exterior through a small

anterior pore. The narrower opening in pit vipers, relative to pythons, results in a better pinhole aperture, while the suspended membrane gives the receptors a lower heat capacity and thus greater sensitivity. The anterior pore equalizes the pressure between the chambers. Both pythons and boas can have multiple pits on either side of the head on the supra- and sublabial scales, while pit vipers possess paired pits, one on each side. The specific morphology of the pits varies and may correlate with the ecology of particular species (e.g., downward facing slits are seen arboreal species).

The infrared receptors contained in the pits (or on the labial scales) are formed from unmyelinated free nerve endings known as terminal nerve masses (TNMs), which are derived from branches of the trigeminal nerve (Goris 2011). Unlike most other sensory neurons, infrared neurons fire constantly at irregular intervals since they are constantly receiving infrared radiation (i.e., background radiation). Stimuli with increased temperature cause increased firing rates, while those with lower temperature cause a reduction in firing rates. In this way, the infrared system acts as a thermal contrast detector (Van Dyke and Grace 2010). Behavioral responses to warm and cold stimuli differ, however, with snakes preferring warm targets.

Signals from the TNMs travel through the trigeminal nerve to a processing center in the medulla (the lateral descending tract and nucleus of the trigeminal nerve) and from there to the contralateral optic tectum (Goris 2011). In snakes, the contralateral optic tectum also receives all of the visual information from the eyes. The optic tectum contains three types of neurons: those that respond to visual information, those that respond to infrared information, and those that respond to both. Both the visual and infrared information are then passed to higher brain centers (nucleus rotundus of the thalamus and anterior dorsal ventricular ridge of the telencephalon), which contain the same three types of neurons. Thus, the infrared and visual sensory systems are intertwined and are thought to produce a combined visual-infrared image. The infrared image is necessarily coarser than the visual one, due to the much smaller

numbers of infrared receptors (thousands compared to millions of rods and cones in the retina); however, the receptive fields of the eye and pits both overlap resulting in a stereoscopic image.

The molecular basis of infrared perception in snakes has been partly uncovered. A temperature-sensitive calcium ion channel, TRPA1, has been identified as a heat-sensing protein expressed in trigeminal ganglion cells in the pits of infrared-sensitive snakes (Gracheva et al. 2010). While TRPA1 is found across vertebrates, its heat sensitivity threshold when heterologously expressed was found to be much lower in pit vipers, pythons, and boas and higher in other snakes that lack infrared receptors. TRPA1 was found to be under positive selection in infrared-sensitive snakes, but not other snakes or vertebrates, consistent with adaptation as an infrared detector (Geng et al. 2011). Based on the phylogenetic distribution of snake species, heat sensitivity of TRPA1 appears to have evolved independently three times. However, the function of TRPA1 alone does not satisfactorily explain the precise heat sensitivity of pit-bearing snakes (Goris 2011), and thus additional work is still needed to explore the molecular basis of infrared sensitivity in snakes.

## Stabilizing Selection

Daniel B. Stamos

National Institutes of Health, National Institute of Child Health and Human Development, Bethesda, MD, USA

## Definition

A type of natural selection that selects against the extreme variations of a phenotype, while selecting for the phenotypic mean.

## Introduction: What Is Stabilizing Selection?

In 1949 I.I. Schmalhausen, summarizing the prevailing theories of stabilizing selection during his time, published *Factors of Evolution: The Theory of Stabilizing Selection*. Here, Schmalhausen writes that stabilizing selection is a form of natural selection in which the phenotypic norm is favored over all deviations from the norm (Schmalhausen 1949). Schmalhausen states that stabilizing selection guards the phenotypic norm from being altered and reestablishes the phenotypic norm when it has been disturbed (Schmalhausen 1949).

Stabilizing selection can be thought of as a powerful force that drives a trait toward the phenotypic mean. There are numerous examples of stabilizing selection in nature. While not as visually striking as directional selection, stabilizing selection plays a vital role in supporting a species' survival, by restricting the deviation from their optimal phenotype for their given environment.

## A Brief Statistical Overview of Stabilizing Selection

By using a bell curve to model the frequency of a given trait in a population, the effects of stabilizing selection over time can be demonstrated (Michigan 2010).

Looking at human birth weight in a population that has not yet undergone stabilizing selection, one can see that most newborns are born with a birth weight near the phenotypic mean (Fig. 1a). However, before stabilizing selection occurs in a population, a significant number of newborns will have a birth weight on either side of the extreme end. Being born significantly overweight or underweight has deleterious consequences for the newborn child and their mother. Thus, over time stabilizing selection will select for the birthweights that fall near the phenotypic mean and against birthweights on the extreme ends (Michigan 2010).

As stabilizing selection molds the population, a new bell curve of the phenotypic frequency of human birthweight will develop with almost all the individuals falling within a narrow range near the phenotypic mean and very few individuals having birthweights near the extreme ends (Fig. 1b). Note in this example it is still possible for babies to be born significantly overweight or underweight after stabilizing selection has occurred, but the relative frequency of babies with those birthweights will be significantly decreased after stabilizing selection.

## Examples of Stabilizing Selection

Nature is full of examples of stabilizing selection. A few prominent examples of stabilizing selection are:

- Tree height
- The prevalence of an intermediate fur color in mice
- Beak size in a bird population
- Human skull size

## Stabilizing Selection and Its Role in Maintaining the Relative Long-Term Stability of a Species

There is an interesting paradox in evolutionary biology. On the one hand species have profound phenotypic stability over geological time, and on the other hand most traits have a lot of genetic variations available to them (Estes and Arnold 2007). Given all the variation available to a trait, evolutionary biologists would expect more fluctuations in the fossil record than is observed. This phenomenon can be explained, in part, by

**Stabilizing Selection, Fig. 1** Stabilizing selection causes the majority of human children to be born at the phenotypically average birth weight. (a) Pre-stabilizing selection human babies are born near the phenotypic mean birth weight. The figure shows that while the majority of children are born near the phenotypic mean birth weight, many children are born significantly overweight or

underweight. (b) Because of the deleterious effects of being underweight or overweight for the mother and child, stabilizing selection will select for children who are born with the phenotypic mean birth weight. Over time, almost all children will be born within a narrow range of birth weights

recognizing the role that stabilizing selection plays in adapting a species to the “long-term constraints” of an environment. Many species have stable interactions with the components of the environment for periods ranging from 1 to 300 million years (Estes and Arnold 2007). This relative stability means that the optimal traits for a given environment remain relatively consistent over time. As a result, for a species to best adapt to an environment, the phenotypic means of a species will mirror the optimal traits for that environment (Estes and Arnold 2007). The stability of an environment places strong pressures against directional selection of a trait, as any deviations from the phenotypic mean is also a deviation from the optimal adaptive traits (Estes and Arnold 2007). Thus, even though there is an abundance of variation for any given trait, most of that variation will be selected against because only a small sliver of that variation falls within the optimal phenotype for a species’ environment.

## Conclusions

Despite being described over 60 years ago, stabilizing selection continues to provide new insights into evolution. While more complex models exist for demonstrating stabilizing selection, a bell curve displaying the frequency of a trait before and after stabilizing selection has occurred is a simple way to show the effects of stabilizing selection on a population. Some people incorrectly assume that natural selection is always driving a species toward new adaptations. But, as evolutionary biologist such as Schmalhausen and Estes have demonstrated, stabilizing selection is a powerful force in maintaining the phenotypic mean. As long as there is an interest in why species have specific phenotypes, stabilizing selection will continue to be relevant in evolutionary biology.

## Stand and Wait Feeding Behavior

Samantha Lantz  
Department of Ecology and Evolutionary  
Biology, Tulane University, New Orleans,  
LA, USA

## Synonyms

[Stand and wait foraging behavior](#); [Stand-and-wait feeding](#)

## Definition

Stand and wait feeding behavior is a strategy utilized by avian predators that stand still in water or on land and wait for prey to approach.

## Introduction

Stand and wait feeding behavior is a common strategy employed by foraging wading birds and is particularly common in visual feeders such as herons (Kushlan 1978a; Meyerriecks 1960). It is characterized by different standing postures and neck positions, but in all cases the predator stands while waiting for prey to approach.

## Description of Behavior

Stand and wait feeding is one of the most common foraging strategies employed by wading birds (Meyerriecks 1960). Typically, foraging predators stand motionless on land, at the edge of a body of water, or in shallow water. When prey approaches within range, the predator strikes rapidly, either seizing the prey or impaling it on its bill. Prey is often swallowed whole. Large prey may be stunned or killed before swallowing, while smaller items are often swallowed live. Strikes (successful or not) are often followed by dipping the bill into the water and then shaking the head.

Because stand and wait feeding behavior is common across a variety of species, it is associated with a diversity of postures and neck positions (Kushlan 1978a). Wading bird posture ranges from a hunched or crouched position to full upright position, with intermediate variations of upright posture in between these two extremes. Similarly, neck posture can result in a head that is retracted or fully extended, or any variation in between. Oftentimes the bill faces the water with the wader peering down, while other times the head is cocked or both the head and neck are tilted (Kushlan 1978a). Head tilting or cocking may be used to reduce glare from the sun (Kushlan 1978a). In addition to the variation in positions and postures, there are also a number of slight variations to stand and wait feeding. For example, stand and wait predators can bait prey while they are waiting by placing a piece of food in the water to attract prey (Lovell 1958). Head or neck swaying are also common additions to stand and wait feeding (Meyerriecks 1962). Stand and wait feeding behavior can be interchanged with other

feeding behaviors, including slowly wading or walking.

Stand and wait foraging is associated with adaptations that may facilitate feeding in a variety of habitats and throughout the day. For example, neck anatomy allows stand and wait foragers to extend the neck rapidly while thrusting for prey. Water depth is an important determinant of prey availability to foraging waders (Gawlik 2002), with foraging wading birds that feed by standing in water restricted by leg length (Kushlan 1976; Powell 1987). Shallow water is generally preferred (Gawlik 2002). Wading birds with shorter legs may also stand on the water edge or perch, for example on logs, rocks or roots. Additionally, wading birds that feed using this strategy often have either white or dark plumage, and it has been hypothesized that either color type can be adaptive towards reducing conspicuousness to prey (Kushlan 1978a). Specifically, white foraging birds may be less visible from below during the day, and birds with dark plumage may be less visible from below at night or when foraging in shadows (Kushlan 1978a). Specialized optics allow foraging wading birds to feed using the stand and wait strategy during the day and at night.

Stand and wait feeding is a common strategy whether foraging solitarily or in groups. Additionally, it is common both in natural habitats (e.g., wetlands, tidal areas) and anthropogenic habitats such as flooded rice fields (Elphick 2000) or canals.

## Conclusion

Stand and wait feeding is one of the most common foraging strategies employed by wading birds. As the name suggests, birds stand “frozen” while feeding, which is in direct contrast to active feeding. This can conserve energy, making stand-and-wait feeding a useful strategy to maximize energy intake (Kushlan 1978b). Resource partitioning based on foraging adaptations, including leg length and temporal feeding strategies, may help to reduce competition among wading birds and to structure wading bird communities.

## Stanley Kuczaj

Heather M. Hill<sup>1</sup> and Holli C. Eskelinen<sup>2</sup>

<sup>1</sup>Psychology Department, St. Mary's University, San Antonio, TX, USA

<sup>2</sup>Dolphins Plus, Inc., Key Largo, Florida, USA

Stanley (Stan) Abraham Kuczaj II was truly an entrepreneur in the broad and diverse field of psychology. Cutting his teeth on human developmental topics such as language acquisition, Piaget's schematas and moderately discrepant events, and culturally influenced development, Kuczaj published profusely on language acquisition and its relationship to play, moderately discrepant events, concept formation, and culture. Influenced by traditional Piagetian approaches, Kuczaj simultaneously believed in the importance of longitudinal studies and cross-cultural generalizabilities. These core themes shaped and recurred across his research and writings, which culminated in a four-decade-long pursuit of trying to uncover the mysterious cognitive worlds of human children and nonhuman animals, especially marine mammals.

Kuczaj was born on 20 October 1950 in Jersey Shore, Pennsylvania to Rose and Stan Kuczaj and was given a childhood nickname of "Sonny." He was the oldest of four children, including two sisters and a brother. His family ultimately landed in Irving, Texas. Truly a success story, Kuczaj earned his GED to attend the University of Texas at Austin where he earned his Bachelor of Arts degree in Psychology and graduated Magna Cum Laude. Kuczaj attended the University of Minnesota, earning his doctorate in child psychology under the guidance of Dr. Michael Maratsos in 1976. His dissertation was a notable and lauded landmark study of the emergence of language from birth to 5. He was awarded the Boyd R. McCandless Young Scientist Award from the American Psychological Association (APA) in 1980.

Kuczaj came to national prominence pursuing fundamental and universal questions about language, thought, and their development in young

children. In 1986, Kuczaj was awarded a prestigious Fulbright Scholarship to work at Oxford University as a Visiting Fellow in the Department of Experimental Psychology where he created life-long collaborations with other language researchers and developmentalists. A voracious reader with a wicked sense of humor and insatiable stream of thoughts and questions, perhaps Kuczaj's greatest gift was his ability to formulate questions about the intertwined roles of language and thought as they shaped the mind of our species and others.

## Language Highlights

Stan Kuczaj began his academic career studying language acquisition, especially verbs. Except, as with all of his work, Kuczaj did not just stop with verbs, he also examined the acquisition of nouns, emotional-based adjectives, relational word classes, and larger categories and classes.

## Verbs!

His dissertation, which incorporated his own children (much like Jean Piaget), focused on the acquisition of verb inflections and entitled “-Ing, -s, and -ed: A study of the acquisition of certain verb inflections” (1977a). With several early publications under his belt, as a preview to his future productivity, one of his most influential papers was derived from his dissertation and published in the *Journal of Verbal Learning and Behavior* (1977b). This paper continues to shape research today, remaining one of his most consistently cited papers (Kuczaj 1977b).

## Extending into Syntax and Semantics

Following the completion of his doctorate, Kuczaj left the frigid winters of Minnesota to return to the temperamental extremes of Texas as a faculty member of Southern Methodist University. Here, he continued to explore children's comprehension and production of new words under a variety

of contexts, managing to publish a number of works and two edited volumes while chair of the psychology department. Publishing in areas that extended current cognitive theories regarding language acquisition, Kuczaj continued to explore the errors and nature of language acquisition. Some key contributions included the papers; “Young children's overextensions of object words in comprehension and/or production: Support for a prototype theory of early object word meaning” (1982a), “Language play and language acquisition” (1982b), “Acquisition of emotion-descriptive language: Receptive and productive vocabulary norms for ages 18 months to 6 years” (Ridgeway et al. 1985), and editing two volumes on language development (1982c, d) in which invited contributors explored and published key papers on language topics that continue to influence language research today. Perhaps even more significant were the perpetuation of themes upon which his language research was founded – play, emotions, culture, and social interactions within his comparative work.

## Developing Through Play

Play was a constant in Kuczaj's research and life. A consummate joke teller and roller coaster connoisseur, Kuczaj's appreciation for play as a major contributor in learning emerged early in his thinking and research. Influenced by Piaget's idea of private (egocentric) speech and Vygotsky's version, inner speech (for a review of these concepts see Alderson-Day & Fernyhough, 2015), Kuczaj laid out a set of hypotheses and research studies regarding the social contexts in which infants and toddlers practiced language skills in his book, *Crib Speech & Language Play* (1983). Distinguishing between crib speech (i.e., self is the model), social/self (i.e., the individual provides the model but is communicating information to another party), social/other (i.e., the child practices the behaviors performed by another individual, the model), and asocial/self (i.e., the child provided the model but is not attempting to communicate with another person that is present), this study was instrumental in supporting the

conclusions that children play with language as they acquire it and appear to prefer to practice it for mastery potentially in private. This study also continues to influence research on language acquisition today.

### Transitioning to Marine Mammals

One of Kuczaj's greatest contributions to psychology was his ability to integrate ideas across disciplines. Appreciative of inspiration from anywhere, Kuczaj's ideas were influenced by different cultures and species; vocal learning in birds influenced his work on the language play in human infants, including babbling, repetition, imitation, and variations on a theme. Piaget's ideas of moderately discrepant events influenced Kuczaj's work on language play and physical play. A fan of travel and experiencing different cultures, the role of culture in language acquisition, thought, concept formation, and eventually nonhuman animal behavior were frequent topics in his work with humans and nonhuman animals. As a leading expert in human language acquisition, Kuczaj was invited to collaborate with another expert in marine mammal cognition, Dr. Louis Herman (1930–2016), who spent over two decades studying dolphin cognition at Kewalo Basin Marine Mammal Laboratory, University of Hawaii at Honolulu. This collaboration produced a number of chapters and articles examining the abilities of dolphins to process semantic information through syntax, such as their article "Responses to anomalous gestural sequences by a language-trained dolphin: Evidence for processing of semantic relations and syntactic information" (1993). This experience was a significant turning point for Kuczaj and his research. Shortly after his time in Hawaii, Kuczaj joined the psychology department at the University of Southern Mississippi as chair (a role he gleefully granted to his peers after 10 years) and established the Marine Mammal Behavior and Cognition Laboratory in 1996.

Representative of the integration of his life experiences, Kuczaj's library held hundreds of books from Piaget's original works to Skinner's *Verbal Behavior* and a translated copy of

Vygotsky's only book to the folktales of Nepal, the history of Kachina dolls, and the interpretation of children's drawings. Within each of these books, notations and underlined passages provide insights into Kuczaj's thinking and formulation of ideas. As Kuczaj was transitioning into the mysterious world of marine mammals, his library also transformed, to include any book that told the "story" of marine mammals. It did not matter if the story was a children's book detailing a friendship between a lost child and a dolphin, Asian/Grecian folklore about dolphins, fictional renditions based off of true stories (Luna the killer whale), or empirically based reference books summarizing the current knowledge of marine mammal physiology, acoustics, distributions, and behavior. They all had important passages ear-marked and notated – his word doodles rather than picture doodles.

No matter the species, Kuczaj always returned to his loves of language and development. His training in developmental psychology and longitudinal, observational studies set the stage for the majority of his work with marine and terrestrial mammals. Kuczaj conducted a variety of cognitive and behavioral animal studies: the development of dolphin calves and their mothers, the development of play, the types of social interactions among different-aged animals, the intricacies of environmental enrichment, the establishment and differences in personality, the importance of contact during social interactions, and the role of emotion in animal behavior. His work in acoustics explored the development of echolocation in dolphin calves, the characteristics of sperm whale codas, the role of individual whistles in mother-calf reunions under experimental conditions, the use of sounds during a cooperative task, and the creation of a two-way system for communication.

### Artificial Language Comprehension

Kuczaj initially applied his extensive language background to marine mammals with Louis Herman at Kewalo Basin Marine Mammal Laboratory. Dolphins were taught arbitrary gestural languages, representing actions (verbs), objects,

and locations to two bottlenose dolphins. The symbolic languages (visual and acoustic) were tested for comprehension, rather than production, of language with two subjects. Using syntactical rules, which varied in order, the dolphins successfully executed these grammatical sequences, revealing flexibility and comprehension.

## Cognition

Through cognition-based tasks, Kuczaj extensively studied problem solving, documented joint attention between humans and marine mammals, as well as tested how animals responded to experimenter given cues. His creative mind aided in developing multiple feeding devices that required problem solving skills or cooperation, as well as visual and behavioral responses to mirrors to locate objects. Empirically investigating the ability for animals to display their creativity was observed in Kuczaj's works with cognition and play. First investigated by Pryor and colleagues, Kuczaj works support the ideology that dolphins can represent past actions and through these representations, can modify previous behaviors to vary their behavior. Additionally, Kuczaj devoted time to understanding how multiple species reacted to novel problems, as well as visual laterality, finding interest in the existence of a dominance function.

Through his works with play, Kuczaj extensively studied enrichment with many species in managed care, focusing on keeping the environment enriching, as well as enrichment being a time to cognitively challenge the animals. This approach provided a balance between training, enrichment, and behavior. Through innovated tasks, dolphins were able to solve novel tasks without the use of training or human influences.

## Play

Kuczaj's works throughout the years empirically investigated play within a variety of different species, uncovering the essential role play fills in their social lives. He was especially drawn to play among dolphin calves, revealing how they

learn about the social norms within the grouping, gain access to other conspecifics, and acquire the cognitive skills needed for play. He extensively studied play in wild and captive dolphins, documenting the roles of peers in cultural transmission, the behavioral variability and individual creativity of play, and the importance of social learning during play of their cognitive development. This was especially apparent through his work with imitation; calves were more likely to imitate peers than adults, including their mothers, highlighting the selectivity of social learning and flexible thinking by young animals.

## Behavior

Kuczaj's diverse interests were fueled through countless collaborations with free-ranging and captive researchers. He valued gaining information about animals in a variety of different settings, advocating the importance of managed care research to gain detailed, sequential observations that can be difficult to acquire in free-range settings while also recognizing the need to understand the same behaviors in the natural habitat. He devoted time to examining behavior with a variety of different species and topics, investigating stereotypic behaviors among wild marine carnivores, seasonal and diurnal patterns, population abundance within the Mississippi sound, contact exchanges between dolphin populations, the influence of group size on social behavior among rough tooth dolphins, epimeletic behavior with a distressed conspecific, and pioneered examining behavior of killer whales in utero. Kuczaj had a passion for all animals, but he had a special love for elephants; his works provided a greater understanding of the role of touch in social interactions and the influence of novel objects on their behavior. Through these behavioral investigations, Kuczaj was fascinated by individual differences. Whether documenting maternal styles or consistent individual differences (e.g., personality), Kuczaj examined how personality in non-human species were affected by time, context, and methodology used (i.e., Five-Factor model, and rating vs. coding). He approached the study of

personality using research conducted in both managed care and free-ranging populations.

## Acoustics

Kuczaj's work with acoustics began with monitoring and evaluating ambient noise in the Gulf of Mexico at varying depths. Kuczaj's passion to understand the specifics of how marine mammals utilized sound was reflected with his works on Audio Evoked Potentials, recording echolocation behavior of free swimming dolphins, examining click trains with echolocation recordings, fine-scale analysis of low frequency, narrow-band calls among dolphins, fractal scaling of echolocation, as well as the behavioral specifics affiliated with different calls (i.e., mothers call their calves, sounds during cooperative behavior). His interest in understanding as much as he could about the marine environment fueled his interest in promoting policy change where possible.

Ultimately, Stan Kuczaj was an advocate for learning from animals in all settings. He advocated for the need for quality zoos and aquariums as they are critical vehicles in helping people understand the importance of conservation. He believed that these programs provide patrons with experiential learning opportunities that would otherwise be impossible, while also leading to a greater appreciation for the environment and understanding of the species.

A prolific scholar, Kuczaj was extremely well published. He had approximately 150 publications and 200 professional presentations and was invited frequently to present keynote addresses at conferences and invited colloquia at other universities. He connected the science and the public, as a featured scientist in a number of world-wild documentaries and magazines like *National Geographic* and *National Geographic Kids*. Kuczaj's ability to blend science with real life anecdotes allowed him to make myriad contributions to the fields of language acquisition, thought, marine mammalogy, and comparative psychology. He encouraged scientists of all bents – acousticians, cognitive psychologists, developmentalists, physiologists, and philosophers, to look at their topics from different perspectives. He persuaded

scientists to remember individuals contribute uniquely and were as important and interesting as consistent group results. He also reminded researchers frequently to go back to the roots – what factors shaped individuals or the species to what they are currently?

He is best remembered for his brilliant mind paired with an enthusiasm and excitement for studying animals. He was a leader in reigniting waning interest in animal behavior and cognition as promoted by Donald Griffin, Niko Tinbergen, Konrad Lorenz, Wolfgang Kohler, Stephen Gould, Ronald Schusterman, and Louis Herman and other animal behaviorists interested in understanding the mind of animals despite not sharing the capacity for language as humans have. He was a leader in all ways from scientific contributions to internal and external leadership positions, including President of the Society for Comparative Psychology and Behavioral Neuroscience, Division 6, of the American Psychological Association (APA), editor-in-chief of the journal, *Animal Behavior and Cognition*, which he founded in 2014, a Fellow of the American Association for the Advancement of Science, APA's Divisions 3, 6, and 7, and the Psychonomics Society, a founding member of the Comparative Cognition Society, and a charter fellow for the Association of Psychological Science. His legacy is carried on by his former students, collaborators, and all those he inspired with his easy-going manner and anything-is-possible attitude.

## Definition

The step reflex is the automatic alternating limb movement response to the stimulus of feet or paws touching a firm surface.

The step reflex, also called the walking reflex, is the automatic alternating limb movement response to the stimulus of feet or paws touching a firm surface. The step reflex is a primitive reflex present in some altricial-limbed vertebrates, and it assists with the development of locomotion ability. In typical development, the step reflex emerges in utero, is present at birth, and disappears in early development. The step reflex has primarily been studied in humans, although there is evidence of this reflex in other species such as cats and rats (Muir 2000).

Locomotion is vital for many organisms to solve many adaptive problems, including acquiring nutrients and escaping predation. Locomotion likely played a significant role in the evolution of a myriad of species, and the step reflex is crucial to the development of movement abilities in some altricial mammals. Altricial and precocial vertebrate nervous systems share the basic circuitry for locomotion, demonstrating that similarities have been preserved throughout vertebrate evolutionary history (Muir 2000). One of the most pronounced differences between altricial and precocial vertebrate locomotion is the developmental delay in movement ability in altricial species. Precocial species are able to locomote voluntarily at birth, thus requiring less parental care, whereas altricial species cannot locomote independently and require more extensive parental care for survival. The mechanisms that activate spinal cord circuitry causing alternating steps or swimming are present in vertebrates at birth; however, brain development in altricial vertebrates is delayed and, therefore, altricial infants require a reflexive response to stimulate the alternating limb movements characteristic of walking, whereas precocial infants are able to locomote voluntarily (Muir 2000).

Humans are a highly altricial species that exhibit the step reflex. The step reflex is organized at the level of the brainstem, whereas crawling and walking require the involvement of the cerebellum and the cerebral cortex (Kolb

and Wishaw 2003). In an adult human, the cerebellum assists with balance, the prefrontal cortex plans movement, the premotor cortex organizes the sequence of movements, and the motor cortex executes the action (Kolb and Wishaw 2003). Humans are born before cerebellar white matter has undergone the most rapid and dramatic period of myelination and before the cerebral cortex is fully developed, so the infant brain is not equipped to control movement as an adult brain does (Kinney and Volpe 2018). As neurological development progresses, at about 2 months after birth, the step reflex disappears and other brain regions take over control of functions related to stepping and locomotion (Yang et al. 1998).

Cats and rats are quadruped altricial species that demonstrate evidence of the step reflex. Robinson and Goldberger (1986) found that kittens less than 2 weeks old that have undergone complete transection of the spinal cord can walk on a treadmill without training while adult cats struggle with motor function after spinal cord transection. It is possible that newborn kittens demonstrate the step reflex in their relatively superior walking ability after spinal cord transection whereas adult cats have already developed the neural pathways that inhibit the step reflex and are therefore unable to recover as quickly. Kittens that underwent this surgery expressed motor control typically not seen until later in development in normal cats, suggesting that this behavior is normally suppressed and may be the result of latent genetic architecture (Robinson and Goldberger 1986). In rats, spinal pattern generators for locomotion are present in utero although rats do not locomote until around 11 days after birth (Westerga and Gramsbergen 1990). Rats are born at a relatively immature stage, demonstrating altriciality in their inability to move about freely at birth. Nguyen et al. (2017) found that when rat pups are held in the air with their hind paws touching a flat and firm surface, at 4 days postnatal, they will reflexively perform a motion similar to walking despite an inability to walk independently. More research is necessary to confirm the presence of step reflex in nonhuman animals.

## Steven Gangestad

Joshua M. Tybur  
Department of Experimental and Applied  
Psychology, VU Amsterdam,  
Amsterdam, The Netherlands

Steven Warren Gangestad is Distinguished Professor of Psychology at the University of New Mexico, where he started working as Assistant Professor in 1987 after completing graduate and postdoctoral training at the University of Minnesota. Steve is renowned as one of the world's leading evolutionary psychologists, with many of his most highly cited papers solidifying the theoretical foundations on which the field is built. Such work includes an account of how cross-cultural variation in behavior can arise from developmental adaptations (Gangestad et al. 2006), a theoretical framework for understanding the variation in sexual strategies that many evolutionary psychologists study (Gangestad and Simpson 2000), and an outline of the evidentiary standards required to categorize features of an organism (including psychological ones) as adaptations, exaptations, or by-products (Andrews et al. 2002). Steve's empirical program has been similarly foundational. It includes pioneering work on facial attractiveness (Gangestad et al. 1994; Scheib et al. 1999; Thornhill and Gangestad 1993), women's gene-seeking versus investment-seeking sexual motivations (Gangestad et al. 2007; Gangestad and Thornhill 1998; Grebe

et al. 2013), and, perhaps most notably, measuring and interpreting variability in sociosexuality (i.e., openness to sex outside of a committed relationship) (Gangestad and Simpson 1990; Simpson and Gangestad 1991). And, as a final category of output, Steve has co-edited volume *The Evolution of Mind: Fundamental Questions and Controversies* (Gangestad and Simpson 2007), which included concise (and, sometimes, productively contentious) pieces by evolutionary behavioral scientists across disciplines, and he co-authored *The Evolutionary Biology of Human Female Sexuality* (Thornhill and Gangestad 2008), which drew from comparative, developmental, endocrinological, and functional perspectives to understand men's and women's sexual psychology.

While Steve has produced work that has touched myriad research programs across the evolutionary behavioral sciences, he has also taken a hands-on role in shaping the direction of the international Human Behavior and Evolution Society (HBES). He served as an elected council member for the society from 1997 through 2003, he was the society's president from 2007 through 2009, and he organized and hosted the society's annual meeting in 2012. Steve's orientation toward drawing from the broader animal behavior literature to study humans was on display at this meeting, where he arranged for a one-day joint session between meetings for the international Animal Behavior Society and HBES.

Steve's most notable contributions – both to scientific societies and to the scientific knowledge on which they are based – are apparent in the field of evolutionary psychology. A glance only toward his articles, books, and service activities in this field can belie his broader involvement in personality and social psychology. Steve's dissertation concerned behavioral genetics, and his first major paper reviewed the nature of discrete classes of personality (Gangestad and Snyder 1985). He has deep knowledge of statistics and psychometrics, and teaches statistics classes at the undergraduate and graduate level. Based on this breadth of knowledge, he has served as Associate Editor for *Psychological Science* – the Association for Psychological Science's flagship journal – since 2012, and he has served as a consulting editor

for multiple other leading psychology journals, including *Journal of Personality and Social Psychology*, *Personal Relationships*, and *Journal of Personality*. And last (but not least), Steve has served as an excellent advisor to many bachelor and Ph.D. students (including the author of this brief biography) – students who are better scientists thanks to Steve’s mentorship.

Steve grew up in Minnesota and returned there for his graduate education after attending the University of Oregon and Stanford University for his undergraduate studies. He currently lives with his wife Sara and son Torin in Albuquerque, New Mexico, with summers and weekends spent in the San Juan Mountains of Southwestern Colorado, which afford much time for hiking and skiing.

## Stimulus and Local Enhancement

Thomas R. Zentall

University of Kentucky, Lexington, KY, USA

## Local Enhancement

Local enhancement refers to the facilitation of learning that results from drawing attention to a locale or place associated with reinforcement (Roberts 1941). For example, Lorenz (1935) found that ducks enclosed in a pen did not react to a hole in the pen that was large enough for them to escape unless they happen to be near another duck as it was escaping. The sight of a duck passing through the hole in the pen may draw attention to the hole. Thus, one could ask if observing a ball roll through the hole, for example, would produce a similar effect. If so, it would not be interpreted as social learning.

Local enhancement may also be involved in John et al.’s (1968, Exp. 1) finding of facilitated acquisition of an aversively motivated hurdle-jump response. Specifically, observer cats that watched a demonstrator cat that had learned to avoid shock by jumping over a hurdle acquired the appropriate shock avoidance response faster than control cats that were trained without having the opportunity to observe the demonstrator. Attributing the copying behavior to local

enhancement, in this case, rather than imitation may not be obvious, but observation of the demonstrator jumping over the hurdle may have simply drawn the observer's attention to the top of the hurdle. In other words, any event that might draw attention to the top of the hurdle (e.g., a ball bouncing over the hurdle or even a light flashing at the top of the hurdle) could facilitate the hurdle-jump response. Similarly, an attentional mechanism may be responsible for the rapid mastery of a V-shaped-fence-detour problem by dogs (the dog finds itself on the inside of the V) when demonstrated by a human (the human moves from outside the apex to one of the arms of the V; Pongrácz et al. 2001). Seeing the demonstrator pass around the end of the fence may draw the observer's attention to the place where it can gain access to the goal on the other side. In general, whenever the performance observed involves an object (e.g., a manipulandum, a hurdle, a barrier) to which the observer must later respond, local enhancement may play a role and appropriate control conditions should be included if one wants to conclude that imitation is involved.

Although performance by the demonstrator may draw the attention of the observer to a location, the outcome of the demonstrator's behavior may also play a role in the observer's tendency to copy. For example, Lefebvre and Palameta (1988) found that pigeons that observed a model pierce the paper cover on a food well to obtain hidden grain later acquired that response on their own, whereas those that observed that same response but with no grain in the well (the model performed in extinction) failed to acquire the response. In this case, the observed behaviors were quite similar for the two groups, but the consequences of the observed behavior were quite different (see also Akins and Zentall 1998). Although one might be inclined to interpret this result cognitively, as the observer's understanding of the consequences of the demonstrator's behavior, a Pavlovian conditioning account in terms of the pairing of attention to a location, and the appearance of a reinforcer, may be sufficient to explain the more rapid acquisition of the target behavior by the observer when the demonstrator's behavior is reinforced. This point will be addressed again shortly.

## Stimulus Enhancement

In the case of local enhancement, the attention of an observer is drawn to a particular *place* by the activity of the demonstrator. The term stimulus enhancement is used when the activity of the demonstrator draws the attention of the observer to a particular *object* (e.g., a manipulandum). Quite often in the study of imitative learning, the object in question is at a fixed location so local enhancement and stimulus enhancement are indistinguishable. In the duplicate-chamber procedure (see Warden and Jackson 1935; Gardner and Engel 1971), however, a manipulandum (e.g., a lever) is present in both the demonstration chamber and in the observation chamber. Under these conditions, drawing attention to the demonstrator's lever might not be expected to enhance observation of the observer's lever. In fact, one could argue that it should retard acquisition of lever pressing by the observer because it should draw the observer's attention away from its own lever. However, the similarity between the demonstrator's lever and that of the observer may make it more likely that the observer would notice its own lever after having its attention drawn to the demonstrator's lever. Thus, stimulus enhancement can refer to the combination of a perceptual, attention-getting process resulting from the activity of the demonstrator in the presence of the lever and stimulus generalization between the demonstrator's and observer's levers. Because it subsumes the effects of local enhancement, the term stimulus enhancement may be more inclusive and, thus, is often preferred (Galef 1988).

Stimulus enhancement may also play a role in mate-choice copying by animals (Dugatkin 1996; Galef et al. 2008). For example, female guppies that see a demonstrator or model female in the presence of a courting male will prefer that male over an alternative male (Dugatkin 1992; Dugatkin and Godin 1992). In this case, it may not be possible to separate the observer's attention to the model female, and therefore to the male nearby, from the putative attraction of the model to the adjacent male.

The facilitation of learning through perceptual factors presents a difficult problem for the study of

imitation in animals. If the similarity between the demonstrator's location or the demonstrator's manipulandum and that of the observer presents an interpretational problem because of perceptual factors, making the location or the nature of the manipulandum for the observer different from that of the demonstrator is likely to interfere with the observer's potential interpretation of the relation between the two tasks. This problem, which will be addressed later, requires a new approach to defining adequate control procedures (see section on the two-action procedure).

## Stimulus Control

Mystra M. Samuelson<sup>1</sup> and Quincy M. Goeke<sup>2</sup>

<sup>1</sup>Animal Behavior Core, Department of Comparative Medicine, The University of Nebraska Medical Center, Omaha, NE, USA

<sup>2</sup>The Institute for Marine Mammal Studies, Gulfport, MS, USA

## Definition

A phenomenon in which a given stimulus reliably elicits a particular learned behavioral response.

*Stimulus control* has been defined by Terrace (1966) as the extent to which a given stimulus determines the probability that a conditioned response will occur. This observed relationship between an antecedent stimulus and behavioral response is measured by examining the change in response probability over time. As the probability of a behavioral response to a given antecedent increases, the behavior is determined to be under stimulus control (Terrace 1966). However, Macintosh (1977) further defined stimulus control as “an observed relationship between changes in external stimuli and changes in recorded behavior” (p. 481). This definition is likewise important, as it highlights a need for two or more conditions which should be compared (Honig and Urcuioli 1981), specifically in the presence and absence of the stimulus.

Stimulus control can be observed by examining the three-term contingency, in which a subject learns to perform an operant response (R) to a discriminative stimulus ( $S^D$ ), resulting in reinforcement/punishment ( $S^{R+/-}$ ; Pilgrim 2015).

**Stimulus Control, Fig. 1** (a) In the absence of an antecedent stimulus (red light), the subject (rat) makes no behavioral adjustment. (b) When the red light is presented, the rat changes its behavior and pulls the lever. Food

reinforcement ( $S^{+}$ ) is delivered as soon as the target behavior is performed. The behavior is under stimulus control once it is only performed in the presence of the stimulus. (Adapted from Skinner 1938)

That is, a conditioned stimulus acquires discriminative control when the desired behavior directly follows an antecedent stimulus. Skinner (1938) demonstrated this concept when a food pellet was provided to a subject (a rat) after performing a lever press in the presence of the antecedent stimulus (a red light), and not when the light was turned off. When the subject elected to press the lever only when the light is on, the behavior was considered to be under stimulus control (Fig. 1). Stimulus control requires that a simple discrimination has been established between the red light, now a discriminative stimulus ( $S^D$ ), and the behavior (R) with the anticipation that the behavior will be rewarded with food as reinforcement ( $S^{+}$ ).

### Establishing Stimulus Control

Stimulus control is established through a process termed *differential reinforcement*, in which a target behavior is reinforced only in the presence of the  $S^D$ . For example, during acquisition, the subject pictured in Fig. 1 would be rewarded for a lever press in the presence of a red light but not when the light is off. Once a discrimination is made, an  $S^D$  indicates to the individual that the associated  $S^{+}$  is likely to occur after the target behavior is performed. Thus, an individual responds differentially to the  $S^D$  than to

extraneous environmental stimuli, called *stimulus discrimination* (Pilgrim 2015).

### Stimulus Control Topography and Stimulus Generalization

Determining if a subject is properly distinguishing the intended  $S^D$  from the extraneous stimuli can be challenging. Therefore, it is critical that the stimuli thoroughly evaluated by examining the *stimulus control topography* (SCT), or the “qualitative differences among members of a functional stimulus” (McIlvane and Dube 2003, p. 195). SCT guides the subject on what to respond to, as well as how to respond (Layng et al. 2011). For example, the rat in Fig. 1 may respond discriminatively to the red light, as indicated by different features of the stimulus such as the hue, brightness, or location of the light. Evaluating stimuli becomes even more complex when individuals focus on different features of the same stimulus. For example, while a rat may develop a discrimination which focuses on the red hue of the light, this may cause them to react to all red stimuli in a process called *stimulus generalization*. The extent to which a behavior can be controlled by variations in a particular stimulus is known as a *generalization gradient*, which can be useful in measuring stimulus control (Pilgrim 2015).

### Response Factors in Stimulus Control

As previously discussed, multiple features of an  $S^D$  may acquire control over responding. The range of stimuli features that are perceived, and therefore can control behavior, is largely dependent on the sensory abilities of the species or individual. Potential limitations for stimuli include visual capacity, audible hearing ranges, physical constraints, or perceivable but – not salient – features. Additionally, stimuli salience has been shown to be influenced, in part, by the type of reinforcement provided (LoLordo 1979). In several species, such as pigeons and rats, visual cues are more likely to be salient and control behaviors in positive reinforcement scenarios, and auditory stimuli are more likely to be salient and achieve behavioral control in negative reinforcement scenarios (Foree and LoLordo 1973; Schindler and Weiss 1982).

In practice, behavior analysts have focused strongly on the association between a target behavior and the subsequent  $S^{r+/-}$ , placing less emphasis on the association between an  $S^D$  and a target behavior (Dinsmoor 1995). This has been evident in the field of animal training, where the emphasis has typically been placed on reinforcement rather than antecedent (Reid et al. 2014). Through evaluating the sources of stimulus control, behavior analysts can adjust the target individual's environment as needed to increase or decrease instances of a targeted behavior.

### Stimulus Control Transfer

Errorless learning techniques provide the subject with guided learning opportunities designed to reduce or eliminate error, which is believed to inhibit the learning process (Terrace 1963a). In these procedures, guiding cues, such as response prompts to the desired  $S^D$ , are transferred to the final  $S^D$  via stimulus fading (Dietz and Malone 1985; Touchette and Howard 1984).

*Response prompts* act as supplemental stimuli, guiding behavior and decreasing errors in the process (Dietz and Malone 1985; Touchette and Howard 1984). Prompts (e.g., verbal or gestural cues, physical guidance, or modelling) are designed to improve behavioral response and are delivered with, or immediately after, the  $S^D$ .

Delayed prompting is a procedure in which the prompt is presented only when there is a delay in behavioral response following the presentation of the stimulus. This is a commonly used errorless learning procedure. If not utilized properly, these tools can create problems for the learner. For example, if prompts are removed too early in the learning process, incorrect response patterns will result (Touchette and Howard 1984).

To establish stimulus control, prompts must be *faded*, *transferred*, or *shaped* properly and with as few errors as possible (Dietz and Malone 1985). In stimulus fading procedures, a target stimulus' behavioral control is acquired by gradually paring the control stimulus with the target stimulus until an association is made. The control stimulus is then gradually eliminated by altering its size, color, or intensity (Fields et al. 1976). In stimulus transfer procedures, stimulus control from the prompt (control stimulus) to the target stimulus occurs using successive pairings of the control stimulus with target stimulus (Terrace 1963b; Touchette 1971). Stimulus shaping procedures involve the subtle changing of the control stimulus over time to slowly create the target stimulus (Dietz and Malone 1985). Additionally, without the effective transfer of behavioral control from prompt to target stimulus, the subject can develop prompt dependency (MacDuff et al. 2001; Reid et al. 2014).

It should be noted that this summary on errorless learning is meant only to introduce the role of learning procedures in stimulus control. This summary is not intended to be a thorough overview of errorless learning, but rather an introduction (for an evaluation of the role of errors in learning see Lauderdale 2015; Maxwell et al. 2001; Poolton et al. 2005).

### Research in Animal Behavior

In laboratory settings, environmental stimulus control has been utilized in order to evaluate auditory discrimination in bottlenose dolphins (*Tursiops truncatus*; Herman and Arbeit 1973), cooperation in humans (Schmitt and Marwell, 1968), and a wide variety of learning procedures in rats and pigeons (e.g., Reid et al. 2014). However, evaluations of stimulus control are also well

applied to understanding the behavior of animals in their natural habitats.

The concept of stimulus control can be applied to evaluations of wild animal behavior in addition to laboratory studies. Specifically, researchers have shed light on the behavioral ecology of animals by evaluating stimulus control. For example, Hansknecht and Burghardt (2010) investigated the visual and chemical cues preceding predatory lingual luring behavior in laboratory reared mangrove saltmarsh snakes (*Nerodia clarkia compressicauda*). Through this evaluation, it was found that antecedent chemical stimuli elicited predatory behaviors and visual stimuli resulted in a weak response rate. Similarly, Iberian wall lizard (*Podarcis hispanica*) demonstrated that antecedent visual stimuli were responsible for stimulating predatory behaviors (e.g., attacks) and chemosensory exploration (e.g., tongue flicks; Desfilis et al. 2003). Examinations of stimulus control on other behaviors such as anti-predatory strategies (Herzog et al. 1989) and maternal behaviors (Farrell and Alberts 2002) in nonhuman animals have led to a greater understanding of the ecology and evolution of various species.

## Conclusion

Stimulus control is integral to the learning process and is a dynamic construct with wide-ranging applications in the scientific and applied evaluations of animal learning. Researchers' and behavior analysts' increased focus on evaluating animal behavior through the lens of stimulus control has broad implications for the study of wild animals, as well as the improvement of welfare outcomes for animals in human care.

## Stochastic Distributions

Chrissy M. Chubala  
Memorial University of Newfoundland,  
St. John’s, NL, Canada

## Synonyms

[Probability distributions](#)

## Definition

A set of observations arising from random or probabilistic processes.

## Stochastic Processes

The term “stochastic” arises from the Greek *stokhastikos*, which means to aim or guess at. Generally speaking, a stochastic process is a random process. In scientific usage, a stochastic process is any process operating over time that can result in several different states or outcomes; the particular state or outcome of the process at any given moment in time is determined randomly, according to some probability function. Thus, the outcome at any moment in time cannot be definitively predicted. Instead, such a process is defined by a mathematical function that describes all its possible outcomes and the probability space that defines their relative likelihood of occurrence.

## Distribution of Outcomes

Because stochastic processes have no single definitive outcome, their outcomes are better conceived of as distribution of possible outcomes and their observed or hypothesized frequencies.

## Stimulus Response

### ► Rodentia Sensory Systems

**An Example** As a concrete example, consider a six-sided die. On any given roll, the outcome could be any one of six numbers. Each possible

outcome has an equal probability of occurring ( $p = 1/6 = 0.167$ ), and it is impossible to definitively predict which outcome will occur on a given roll. Thus, the roll of the die is a stochastic process.

If the die were to be rolled a large number of times, a distribution of the observed outcomes could be plotted. Figure 1 gives the results of 100 rolls of a die. In the left panel, the frequency of occurrence of each outcome is given as a histogram; in the right panel, the probability of obtaining each possible outcome is displayed in a line graph. Both graphs are different ways of conceptualizing the same stochastic distribution. Note, in the right panel, that the probability of each outcome's occurrence hovers around 1.67, in line with the probability function underlying the stochastic process of a die roll. As the number of observations increases, the probabilities observed from a stochastic process will come to

more closely reflect the probability function underlying the process.

Theoretical Distributions

In the example above, the stochastic distribution in question was one observed from real world phenomena. Such stochastic distributions can likewise be seen in data from experiments in animal cognition, provided the observations are derived from processes with some random or probabilistic components. However, the reader may also encounter stochastic distributions in more theoretical settings, such as computational models or statistical tests.

**Stochastic Distributions in Computational Models** When modeling animal cognition, it is useful to assume that there is a random or stochastic element to behavior, in order to accommodate

S

**Stochastic Distributions, Fig. 1** Stochastic distribution resulting from 100 rolls of a fair six-sided die, presented as both a histogram of outcome frequencies (left panel) and a distribution of outcome probabilities (right panel)

differences between individual animals or individual trials, or to minimize researcher bias. Researchers will thus hypothesize an underlying distribution from which they randomly draw parameter values. For example, drift-diffusion models (e.g., Ratcliff 1978; Ratcliff and McKoon 2008) assume that the speed with which a participant comes to a decision (i.e., reaction time) depends upon a random sampling of drift rates from a normal distribution with a defined mean and standard deviation. Model fitting techniques are used to determine the exact shape of the distribution. As shown in Fig. 2, some examples of theoretical distributions often used in computational models include:

**Uniform distribution.** A continuous or discrete distribution in which every outcome is equally likely to occur, as in the die roll example above.

**Normal (Gaussian) distribution.** A continuous distribution in which the peak probability of occurrence is centered around some mean, with some standard deviation describing the steepness of the (symmetrical) curve away from the mean.

**Exponential distribution.** A continuous distribution that describes the time between events in a process that unfolds at a constant average rate. The probability of an event occurring is a function of the average rate and the passage of time.

**Ex-Gaussian distribution.** A continuous distribution that describes the sum of a Gaussian and an exponential distribution. This type of distribution is often used to model and describe reaction time data, which have been argued to comprise an exponentially distributed decision process and an approximately normal distribution of the duration of various cognitive operations. Ex-Gaussian distributions look like normal distributions with positive skew, due to their exponential component.

**Stochastic Distributions in Statistics** The ultimate objective of a scientific experiment is to say that some result is true, given some manipulation. Although the goal is to demonstrate that the result is true for the whole population of interest (e.g., all rats, all female humans), an experiment is necessarily limited to demonstrating that the result is true for the particular sample it tested. Instead, statistical techniques make use of stochastic

**Stochastic Distributions, Fig. 2** Density graphs of random sampling from four stochastic distributions often used in computational models. Parameters for the random

sampling are given below each panel. Note that as  $N$  increases, the density graphs more closely approximate the underlying probability function

distributions to estimate the result in the larger population. Statistical distributions use the mean and standard deviation obtained in the sample to estimate the mean and standard deviation in the population, provided certain assumptions are met. Although different statistical tests carry different sets of assumptions, all tests assume that the observed sample was selected at random from the population and assigned randomly to different treatment groups. Provided the assumptions are met, statistical distributions allow researchers to determine the likelihood that the effect observed in their sample reflects a real effect in the population. Some common types of statistical distributions include the Student's *t* distribution, the *F* distribution, and the Chi-Square distribution; these are most commonly used with the Student's *t* test, the *F* test, and the Chi-Square test, respectively.

## Stone Tools

Michael Haslam  
University of Oxford, Oxford, UK

## Synonyms

[Animal tool use](#); [Archaeology](#); [Behavioral evolution](#); [Lithic technology](#); [Primate behavior](#)

## Definition

A stone tool is a single, typically moveable piece of rock that is used by an animal to effect a change on its environment. The rock may be modified before use and may be used, either attached or unattached to other objects, as one part of a multi-component tool system.

## Introduction

Because of their durability and ubiquity in the human archaeological record, stone tools are the central piece of evidence available for the long-term study of human behavior. The earliest known stone implements date back 3.3 million years in Lomekwi, Kenya, and they have been used by human societies up to the present day. The hard surfaces and ability to form a cutting edge that rocks provide have made them invaluable for tasks such as pounding, slicing, scraping, and grinding and for the formation of symbolic objects.

The importance of stone tools to human evolution has increasingly made them a target for comparative observations and experiments in nonhuman animals (hereafter, animals). Particularly among primates, but also other animals such as corvids, stones have been used in studies of social transmission, behavioral ecology, and physical cognition and as analogies for the development of human behavior. In both wild and captive settings, stone tools have formed the basis for the exploration of cultural capacities in animal groups. In this entry I focus on wild activities – those observed among animals in their natural habitats rather than in zoos, laboratories, or sanctuaries – although the influence of captive studies will also be considered.

## Why Use Stones?

Stones have two main qualities that render them effective tools: they are abundant and durable. Rocks are typically available on or near the surface of all parts of the planet, excluding those that

have high levels of sediment or ice buildup, such as river floodplains and glaciers. Unlike other tool materials such as plants, they can be found from the tops of mountains to the depths of the ocean, making them accessible to all forms of animal life. Stones also naturally weather into a variety of sizes, from silt and sand to pebbles and boulders, which means that animals of all sizes can manipulate them.

Stones range in hardness from those that usually crumble under slight pressure, such as mudstones, to those that will withstand repeated impacts, such as basalt and granite. The durability of the latter means that they can be relied upon when needed as a tool, which in turn allows for tool use to become entrenched within a given animal's behavioral repertoire. An additional property of some rocks, that they can be conchoidally fractured to produce useable sharp and robust cutting edges, appears to have been discovered only by members of the human lineage (the hominins) since our split from other African apes over 6 million years ago. However, as discussed below, recent discoveries among wild capuchins suggest that production of sharp-edged stones is not unique to humans.

### Stone-Tool-Using Animals

Comprehensive surveys of tool-using animals that include anecdotal accounts exist elsewhere (Shumaker et al. 2011), and the current discussion is therefore intended to be informative rather than exhaustive. Most attention has been directed toward primate use of stone tools, driven initially by observations among East African chimpanzees (*Pan troglodytes schweinfurthii*) in the latter half of the twentieth century (Goodall 1964). The Gombe Stream National Park chimpanzees threw rocks in an aggressive manner toward researchers and baboons, although they did not otherwise use stones as tools. It was only later discovered that some communities of West African chimpanzees (*Pt. verus*) habitually used unmodified stones as handheld hammers to break open encased nuts (Boesch and Boesch-Achermann 2000; Matsuzawa 2011). The fact

that these communities cluster around the junction of modern-day Ivory Coast, Guinea, and Liberia, while other well-studied West African groups such as the Fongoli chimpanzees do not appear to use stone tools, suggests that stone pounding emerged independently in that region, perhaps as recently as a few hundred thousand years ago (Haslam 2014). In any case, the geographical, phylogenetic, and functional restriction of chimpanzee stone tool use to nut-cracking in *Pt. verus* indicates that it is likely a specialized, derived behavior in this subspecies. Recent reports of West African chimpanzees accumulating rocks in and around specific trees, accompanied by displays that include drumming and vocalizing, add an interesting although as yet under-explored component to this picture (Kühl et al. 2016).

The possibility that chimpanzees and humans shared a common, stone-tool-using ancestor is diminished by the absence of such activities among the second *Pan* branch, bonobos (*P. paniscus*). Similarly, there is no evidence as yet of wild stone technology among the other great apes: gorillas and orangutans. Moving further out along the primate family tree, the next species that has been observed to commonly use stone tools under natural conditions is the long-tailed macaque (*Macaca fascicularis*) of Southeast Asia. Macaques in coastal areas of both Thailand and Myanmar use stones to break open a wide variety of shoreline species, particularly shellfish such as oysters and gastropods living in the intertidal zone (Gumert and Malaivijitnond 2013). While the gastropods are cracked open on an anvil using a handheld hammerstone, similar to chimpanzee nut-cracking, oysters are opened using precise strikes onto the shell, while they remain attached to a rocky substrate. This behavior requires the macaques to strike not just downward, as West African chimpanzees do, but sideways and occasionally even upward to access an oyster. Macaques do also crack nuts, especially the sea almond (Falótico et al. 2017), but their focus on animal, often mobile, prey differentiates them from other stone-tool-using primates. Their geographic and phylogenetic separation from the African great apes indicates that they too have independently converged on this behavior.

Moving across to the New World monkeys, the final species of known habitual stone-tool-using primate is the bearded capuchin (*Sapajus libidinosus*). These animals predominantly use their tools to crack open encased nuts, fruits, and seeds, including some with relatively hard shells that require full-body extension to raise a pounding stone to the required height before striking (Visalberghi et al. 2015). However, some wild capuchin groups have also developed the use of stones as aids when digging for underground foods such as arachnids and tubers and for directly percussing a handheld stone against a stationary rock, fracturing the former and releasing quartzite dust (Falótico and Ottoni 2016). The fracturing behavior, termed stone-on-stone (SoS) percussion, produces sharp-edged, conchoidally fractured pieces that possess the same technological characteristics as early human flaked tools (Proffitt et al. 2016). However, the capuchins do not use the sharp flakes, instead licking and sniffing at the dust released by their activities for reasons that are currently unclear. Female capuchins may also engage in aimed stone throwing to attract the attention of males as a form of sexual display which, along with SoS percussion, provides examples of non-foraging-related use of rock tools. Given that tool use among wild platyrrhines is very rare, the evolution of these behaviors is a further example of primate convergence on stone technology.

Outside the primates, there are few examples of habitual use of rocks as tools. However, those that have been observed offer insights into the ways that stones can be aligned with the anatomy and activities of non-primate species. In birds, for example, Egyptian vultures (*Neophron percnopterus*) have repeatedly been observed using their beaks to drop or throw stones onto ostrich eggs to access the yolk inside. This behavior has been suggested to be prompted by environmental cues rather than strongly heritable or learned (Carrete et al. 2017). Dropping as a means of opening encased foods is more widely spread among birds, although in most cases, it is the food that is dropped rather than a stone, which under current definitions does not make this activity tool use. Nevertheless, by dropping food onto stone

anvils, birds make use of a specific part of their environment that requires precision and planning, much the same way that stone tool use does. For example, groups of wild New Caledonian crows (*Corvus moneduloides*) repeatedly drop candle-nuts onto the same stone blocks (Hunt et al. 2002), suggesting that these stone anvils are selected for their usefulness. A similar anvil-based behavior has been reported for wild tuskfish (*Choerodon* spp.) in breaking open molluscs and other prey (Harborne and Tholan 2016).

The most prolific wild non-primate stone tool user is the sea otter (*Enhydra lutris*). Members of this species that specialize in feeding on tough-shelled prey such as marine snails and bivalves are most likely to employ rocks during foraging, partly as a result of high encounter rates with these prey (Fujii et al. 2015). The otters typically dive to collect their prey from under the water but return to the surface to feed while lying on their back. On occasion, otters also bring up a stone that they hold on their chest and strike the prey against, while stones also may be used as paw-held hammers. Genetic studies show that relatedness is not one of the main determining factors for whether an individual sea otter uses tools (Ralls et al. 2017), but instead this behavior may be a result of competition among specialized mollusc feeders.

As noted, rocks come in a variety of grain sizes, which has enabled some smaller invertebrates to become stone tool users. Notable among these are the corolla spiders (*Ariadna* sp.) of Namibia, which arrange a circle of usually 7–8 quartz grains around their burrow. These grains are typically less than a centimeter in width, and the spider attaches a taut thread to each of them as a means of detecting any prey that disturbs the circle (Henschel 1995). The fact that the spider first positions, and then is in remote contact with, each stone qualifies this behavior as tool use, although it differs from the percussive activities prevalent in other species. A second invertebrate example of stone use is found in the larvae of flies such as *Myrmeleon* sp., known as ant lions, who project sand grains toward prey (Pierce 1986). The result is to cause the prey to fall into a conical pit that has been previously been excavated by the

ant lion, enabling capture. Habitual stone tool use for non-foraging activities has yet to be described in an invertebrate species.

## Stone Tool Function

Leaving aside the symbolic and cutting functions associated with hominin lithic technology, the primary use of stone tools is force transmission and amplification. The most common targets of mammalian (primate and sea otter) rock use are encased foods, including nuts, seeds, and molluscs, that are difficult or impossible for the animal to open using only its teeth and hands or paws. For those capuchin groups that engage in the practice, digging activities also involve percussion, in that the stone is used to forcefully break up tough sediments and assist with enlarging holes. The same purpose underlies Egyptian vulture stone tool use and indirectly applies to those species such as New Caledonian crows and tuskfish that drop or throw food onto specific stone anvils. Capuchin SoS percussion does not have an intermediate target such as a nut, which means that even greater force is transmitted between the hammerstone and the underlying anvil or passive stone, contributing to the likelihood of hammerstone fracture (Proffitt et al. 2016).

Force transmission is relevant to those species that throw or project rocks toward targets. The high density of many stone materials ensures that they are less affected by air friction or winds during their flight than other materials such as leaves or grass. This characteristic means that the force imparted to the stone by the thrower is more readily transferred to the target on impact, as seen in the case of ant lions or chimpanzees. The West African chimpanzees that accumulate stones around trees may also be making use of force transmission to generate loud noises from the contact between the stone and tree trunk or buttresses. Throwing stones is therefore typically not a stealthy activity, even leaving aside direct contact with an intended target, and this feature is exploited by capuchins during sexual displays. Even a stone that misses its target will usually

cause a disturbance that startles the target and draws its attention toward the thrower, which is the apparent intention of female capuchins.

The case of corolla spider stone tools is unusual in that, while it is still foraging-related, it does not involve the stone directly amplifying or transmitting a force from the user to the target. Instead, a passing prey animal causes vibrations in the arranged quartz grains, which in turn alert the spider to its direction and proximity through the attached web strands. In this manner the corolla spider incorporates stones into a multicomponent compound tool, built to serve the same vibration-based detection strategy practiced by many web-spinning spiders.

## Stone Tools and Animal Cognition

The implications of stone tool use for animal cognition have been investigated for several decades, both because of its potential relevance for comparative studies with human cognition and for the study of animal behavior in its own right. One of the common features that apply to all known stone-tool-using animals is the selection of appropriate materials from a heterogeneous background of available rocks. For example, both bearded capuchins and West African chimpanzees in their natural habitats have been shown to match the weight and material (and thereby density) of a hammerstone to the toughness of the nut that they need to break open (Visalberghi et al. 2015). Wild long-tailed macaques in Thailand also select larger stone tools to open larger prey items (Gumert and Malaivijitnond 2013), and Egyptian vultures preferentially throw smooth over jagged pebbles at ostrich eggs (Thouless et al. 1989). Such selection does not necessarily require complex brains, as the width of the quartz grains arranged by a corolla spider also closely tracks the spider's body size and the diameter of its burrow (Henschel 1995). This universal selection process derives from the fact that not all stone materials are suitable for all tasks. Tool selection is therefore often likely to be driven by the functional fit between a rock's affordances, an animal's physical capability, and

the required outcome, rather than a conscious decision-making process.

Rocks that are suitable for use as tools are not always available in the immediate vicinity of the site where they are needed, so all wild stone tool users also transport materials. Transport distances can range from centimeters in the case of the corolla spider to tens or hundreds of meters for monkeys and vultures, to kilometers for chimpanzees (Luncz et al. 2016), although in each case the cumulative effect of multiple movements through time may increase the overall distance that a given tool travels. Transport costs can also affect stone selection, for example, wild capuchins have been experimentally shown to transport lighter stones when the subsequent travel distance to an anvil is extended (Visalberghi et al. 2015). Both hammer and anvil stones are transported by wild capuchins cracking cashew nuts in Brazil, chimpanzees breaking palm nuts in Guinea, and sea otters in the eastern Pacific (Haslam et al. 2017). Anvil transport has yet to be documented in wild macaques, although its future discovery by researchers or innovation by the macaques cannot be ruled out. In the case of both selection and transport, an animal needs to be able to recognize technically salient aspects of the available rocks, including characteristics such as density that may not be immediately visually obvious. The solution employed by most animals is haptic, by touching, moving, and sometimes lifting a potential tool in order to assess its suitability.

Collectively, the selection and transport of rock material to tool use sites is part of a process by which these materials are incorporated into what has been described as a body-plus-tool system (Mangalam and Frigaszy 2016). In this scheme, tools become an embodied part of the animal's perception of itself, in effect meaning that feedback (such as vibrations and shifts in tool weight distribution) is experienced by the animal as occurring to a part of its own body. This kind of material cognition may even extend to the environmental niches created by tool-using animals, as they repeatedly bring objects and the targets of tool use together in specific locations on the landscape (Mosley and Haslam 2016). The long-term durability of stone tools and anvils means that

such collection points both lower the costs of assembling such sites for future tool users and provide a scaffold for the more rapid learning or adoption of tool use by juvenile group members. In wild stone-tool-using primates, this learning process typically involves years of play and practice before full proficiency is achieved, while in corolla spiders and Egyptian vultures, the behavior appears to occur spontaneously.

## Stone Tools and Social Behavior

Beyond documenting the development of individual skills, stone tools have assisted with investigations into the emergence and spread of group-specific behaviors. Where these behaviors extend in time and across multiple individuals in an interacting group, they can be considered traditions, and sets of traditions that differentiate one group or community from another may be labeled animal cultures. Experiments with captive animals, particularly chimpanzees (although not necessarily of the West African subspecies), have repeatedly demonstrated how social transmission of novel behaviors can occur (Whiten 2017). Cultures and traditions can involve any aspect of shared, learned behavior, from vocalizations to social interactions (McGrew 2004) but of relevance to the current instance are those involving rocks.

Wild West African chimpanzees confronted with natural and artificial stone tool selection tasks have demonstrated an ability to learn by observing the actions of others. This spread of social knowledge has involved both the foods suitable for targeting with such tools (Biro et al. 2003) and the materials suitable for use at a given time (Luncz and Boesch 2014). Use of digging rocks by wild capuchins at Serra da Capivara National Park (SCNP), Brazil, but not by groups of the same species at the Fazenda Boa Vista site (which instead dig using their hands), may also be a result of social traditions within these communities. When combined with other differentiating activities that have no clear ecological drivers, such as stick tool use among the SCNP capuchins (Cardoso and Ottoni 2016), the collected suite of

distinguishing behaviors suggest that bearded capuchins also exhibit cultural norms. The cultural mechanisms and patterning of New Caledonian crow tool use are subjects of a currently unresolved debate, although these discussions concentrate on plant tool manufacture and use, and stone anvil use has yet to be examined in this light.

Research into sea otter stone tool use has not found social learning to be an important component of this behavior. Instead, individual learning tied to familiarity with prey species that require or benefit from technological processing seems to be more important determinants. Given that feeding preferences can be transmitted from mother sea otters to their children, tool use may also be indirectly transmitted within specific lineages, but clear evidence for such technological transmission is currently lacking, and group-specific tool use traditions have yet to be identified in this species (Fujii et al. 2015). Vulture rock throwing has seen less research intensity, but both individual and social learning strategies are unlikely explanations for this activity (Carrete et al. 2017). Instead, personality traits that differ between individuals may result in reinforcement of stone tool use in some vultures but not in others, building on a natural propensity for dropping smooth objects. Neither corolla spider nor ant lion tool use has been studied in sufficient detail to discern traditional or cultural patterns, and at present these are assumed to be expressed with little variation by naïve individuals.

Studying behavior in animals removed from their natural environmental and social settings is problematic, especially when the overwhelming influence of human captors is taken into account (Haslam 2013). However, studying animals in laboratory contexts can, at times, allow for researchers to investigate variables that might influence stone technology in a more controlled manner. For example, caged capuchin monkeys spontaneously broke stones that were provided to them by experimenters in a laboratory, in the absence of any immediate need for such broken pieces (Westergaard and Suomi 1994). One of these captive animals also used stones to cut through an acetate barrier to reach a food reward,

on occasion breaking the stones to reduce them to a useable size. Similarly, captive bonobos raised as members of an ape-human collective also were encouraged to break stones in order to obtain a cutting edge and get a food reward (Whiten et al. 2009). With practice, these animals were able to remove small, sharp-edged flakes from a larger stone core, although the total assemblage of broken stones that this activity produced were readily distinguishable from those produced by ancient hominins. A juvenile zoo-housed orangutan was also successfully encouraged to break and use stones to cut a cord and retrieve food (Wright 1972). No captive or wild animal of any species is known to have spontaneously flaked and then used cutting stones without human intervention and encouragement, although judging by attempts to date, it is likely that an individual could eventually be trained to produce and use simple stone assemblages that mimic hominin flaking.

Using captive animals to investigate the development of behaviors that naturally occur within their own species, rather than attempting to get them to imitate hominins, adds a level of ecological veracity. For example, chimpanzee social learning of nut-cracking with stone tools has been demonstrated under captive, sanctuary conditions (Whiten 2017). This work showed that, provided individuals had reached a similar age to that seen among proficient wild West African chimpanzees, socially observing nut-cracking increased an individual's own nut-cracking activities. The East African chimpanzee subspecies (*P. t. schweinfurthii*) studied in this experiment does not presently use stone tools in the wild, which lends further weight to the conclusion that wild chimpanzee nut-cracking in West Africa is derived and cultural rather than solely genetically mediated.

Social transport and use of rocks results in the nonrandom accumulation of durable materials across a landscape. While the actions of a single individual may be difficult to identify and interpret, the repeated activities of a social group build up an often unintended but distinctive assemblage of related tools. This basic principle underlies the search for and analysis of sites created by hominins over the past few million years (see

below), enabling their archaeological investigation. However, since the start of the twenty-first century, archaeologists have increasingly turned their attention to the stone assemblages left by wild animals, building on prior work that recognized the value of reconstructing chimpanzee behavior from widespread and patterned activities such as nest building (Stewart et al. 2011). Initially conceived of as chimpanzee or primate archaeology, and at present still dominated by excavations and analysis of primate stone pounding behavior, this work is growing to encompass other stone tool using species (Haslam et al. 2017). Although in its early stages, this practice adds an extended temporal dimension to the behavioral work on wild primates conducted over the past 50 years, enabling direct investigation of topics such as the longevity and geographical spread of stone tool traditions and the identification of tool use in vanished animal populations.

## Human Stone Tools in Animal Context

This section summarizes the major trends in hominin lithic technology, as currently understood, in order to contextualize the preceding discussion of animal stone tool use. The key difference between the two is that members of the human lineage developed a reliance on breaking stone tools to form either useful edges or intentional shapes. While hominins have also likely used pounding tools for force amplification throughout our technological history, those tools are often difficult for archaeologists to distinguish from naturally occurring rocks. Advances in the study of use-damage patterns on pounding tools hold promise but are in their infancy when detecting early percussive stones (Haslam et al. 2017). The story of human stone tool use is therefore almost exclusively derived from flaked stones, including assessments of cognitive and manual abilities and social information transmission.

As noted, the earliest known flaked stone tools come from the 3.3 million-year-old Lomekwi 3 site in Kenya (Harmand et al. 2015). These

tools were accompanied by large rocks that were interpreted as anvils, suggesting that the flakes were broken against those anvils rather than being made by striking one handheld rock against another. The site predates evidence for members of the *Homo* genus by half a million years, leaving a species of *Australopithecus* or *Kenyanthropus* as the most likely creators. A 3.4 million-year-old site in Ethiopia also has evidence for animal butchery using stone tools, although in that case the cut-marked bones, rather than the tools themselves, were recovered (McPherron et al. 2010).

There is no reason to assume that, once Lomekwian technology was invented, all hominins used flaked stones for the subsequent 3.5 million years. The early stone record is very patchy, and the next identifiable flaked stone tools after Lomekwi date from much later at 2.6 million years ago. These simple broken cobbles are part of the Oldowan tradition, named after the early archaeological site of Olduvai Gorge in Tanzania. *Homo habilis* is assumed to have produced at least some of the Oldowan, although contributions from contemporaneous australopiths cannot be ruled out. Humans continue to make and use simple flaked stones right up to the present day, with additional, more complex, stages added onto this foundation.

The second major step in hominin lithic technology was the deliberate shaping of large tools to produce cutting and chopping edges, sometimes with symmetrical shapes. This tradition is called the Acheulean, after the French site of Saint-Acheul, and it emerged around 1.7 million years ago. This timing roughly coincides with early records of *Homo erectus*, who had a much enlarged brain compared to prior hominins, and there are strong associations between this species and the Acheulean at a number of sites. Like the Oldowan, much of the Acheulean is assumed to have been targeted at carcass processing, as meat increasingly entered hominin diets. *H. erectus* was the first hominin to range widely across the Old World, and its enhanced technological skills would have been a crucial part of that process.

The final major step in hominin stone technology starts at different times in different places but was underway by around half a million years ago.

At that point a number of *Homo* species were emerging in Africa and Eurasia, including *H. neanderthalensis* and the Denisovans, and the complexity and interbreeding revealed by recent genetic studies suggests that we should be cautious in assigning any one tool tradition to a given species without direct fossil association (Stringer 2016). Variously known as the Middle Stone Age or Middle Paleolithic, this stage involved creating smaller, more complex stone tools that were likely combined into composite tools such as spears and hafted scrapers. In some parts of the world, such as Europe, the more recent parts of this tradition involved long stone blades and tiny microliths (these form part of the European “Upper Paleolithic”), but these are not universal developments and cannot be generalized to other regions.

The overall trend in human lithic technology is the development of tool forms that require more precision and more planning in their manufacture and the development of a toolkit that joins stones to other materials using adhesives and binding. Force transmission remains a central part of the function of these tools, including through the focusing of human strength into small surface areas such as a thin cutting edge or the tip of a spear. However, tasks such as scraping and shaping require more precision and modulation of force than simple percussion. It is also clear that humans began imbuing their tools with symbolic meaning, that is, the stones played a role in a wider worldview that was not solely determined by tool shape, material, or usefulness. The origins of symbolic thought are debated, but they were present at least 100,000 years ago.

The human lineage has converged on the same role for stone tools as each of the other animals discussed above. They are used to change human muscular force into an amplified, concentrated, or spatially transmitted form, and they are used as parts of multicomponent tools. Human tendency toward tool use appears to be innate, as in the other species, except that humans rely on object manipulation and combination to a much greater degree than in other species, and they bolster this process with knowledge storage mechanisms underpinned by language. That said, modern humans do not automatically develop the ability

to make even simple Oldowan tools, and like the other tool-using primates, they have to go through a learning period involving repeated trial and error in a social context. It is therefore most likely that earlier humans required the same learning process, during which skills such as the ability to select and transport the correct raw materials were honed.

In this light, the essential difference between human stone tools and those of the mammals, birds, and invertebrates is an ability to derive seemingly innumerable novel technological solutions to risky problems. Humans developed a toolkit that combined stone-, plant-, and animal-derived tools and became reliant on that toolkit to survive in the varied environments into which they dispersed. Animal tool use is, on the other hand, built on specific tools for specific tasks, with little to no flexibility in how those tasks are performed. The animal approach ensures a high degree of success in tool use activities, but it limits those activities to locations with appropriate materials for practice and performance. Human cooperation and reliance on social information enhances the speed and efficiency with which we learn about the affordances of objects around us, although again this is likely to be a difference of degree and not kind, at least when compared with other mammalian stone tool users.

## Conclusion

The usefulness of rocks for force amplification has been discovered multiple times among the primates and in a small number of other taxa. Considering the ubiquity of stones at all time periods, it is probable that the pounding, throwing, and force transmission behaviors seen among living animals were also present in extinct species and in prior members of extant lineages that no longer use such tools. However, recovering evidence of such activities will require further investigation into the use-damage patterns that they would leave on the tools. Where we might currently expect stone tool use but find none – in East African and Central African chimpanzees, for instance – then archaeological research may well

turn up evidence for such use in ancestors of those species living thousands or millions of years ago. Loss of stone technology, which may have happened several times among various early hominins, needs investigation just as much as its innovation and spread.

Inventive, non-primate taxa such as wild octopuses, elephants, cetaceans, and corvids are targets for further research into possible stone use. Given the addition in the past decade of well-studied taxa such as wild capuchins and macaques to the known stone-tool-users club, and the comparatively limited investigation of such behavior among invertebrates and aquatic animals, we can be certain that additional wild species will be found using stone tools in future. Of particular relevance to that search will be those animals that consume encased foods or whose foraging can be performed more efficiently by forcefully breaking down barriers. Animal stone tool use has probably always been a rare behavior, with its associated costs of tool selection and handling, but the variety of living species that have converged on it indicates a solution that will have emerged time and again throughout the history of animal life.

### Synonyms

[Behavior plasticity](#); [Phenotypic reversibility](#);  
[Reversible plasticity](#)

### Definition

Concept that behavioral and phenotypic adaptations are plastic, or flexible, in the environment and can induce or retract their expression.

### Introduction

For every adaptation or strategy developed to maximize an animal's fitness in the wild, there is also the capacity for the reversal of these traits. Strategy reversibility is a phenomenon that can

occur on different temporal scales and via different mechanisms. Depending on the context, reversibility can be morphologically or behaviorally phenotypic, can involve temporal scales from seconds to thousands of years, and can be responsive to environmental conditions.

## Reversal of Traits in Response to Environment

To fully understand the scope of phenotypic plasticity, and therefore strategy reversibility, organisms must be exposed to and observed in environments with changing factors. An experiment that tested predator-induced plasticity in gray tree frog (*Hyla versicolor*) tadpoles revealed that the differences in development were considerable depending on whether or not tadpoles were exposed to predation in their early developmental stages (Relyea 2003). The phenotypic differences observed were both behavioral and morphological in nature as the tadpoles adapted to potential predators in their environment. Differences included responses in activity level, whereby tadpoles that were exposed to predation during early development reduced their activity level considerably and spent a greater amount of time hiding compared to their counterparts without predator exposure. Tadpoles that changed their behavioral strategies in response to predation were more likely to survive to adulthood than tadpoles that did not adapt different behavioral strategies. Upon removal of the threat of predation in their environment, tadpoles were most likely to return to normal patterns of behavior.

Morphological adaptations were less plastic in that the deeper tail fins, shorter bodies, and greater mass developed by tadpoles exposed to predation were not as quickly reversed as behavioral adaptations were. Animals will also respond with plasticity to an environment that has had a new prey item introduced, but in different ways than those exposed to predation (Gabriel et al. 2005).

Reversibility of traits in the natural habitat of these tadpoles would most likely not only affect the individuals of the species but would also have an effect on the ecological community as well.

An introduced stimulus will affect phenotypic and behavioral strategies for as long as the stimulus remains in the environment and may have collateral effects on other species or resources in the same area. However, reversibility of traits is only utilized when it is necessary to advance the survival value of the individual.

## Strategy Reversibility and the Rise of Mammals

Strategy reversibility may have played a role in the adaptations mammals developed following a massive extinction event that lead to a decrease in predation. Preceding this extinction event, mammals likely adapted to nocturnal behaviors in order to avoid larger, diurnal predators. Following the mass extinction of these larger predators, some nocturnal mammal species may have reversed to diurnal behaviors because nocturnal behaviors were no longer necessary or beneficial for the survivor of the individual (Relyea 2003).

## Conclusion

Strategy reversibility is not only a necessary mechanism with which to adapt to a changing environment but also it may exemplify evolution manifesting itself through reversal of survival strategies, phenotypic traits, or behavioral patterns to maximize the probability of species persistence. Being able to display plasticity and flexibility of traits has significant survival value for the majority of species.

## Stress

Richard May  
Biology Program, Southern Oregon University,  
Ashland, OR, USA

## Definitions

Stress may be generally defined as a real or anticipated threat to an organism's ability to regulate its internal environment. Stressors are specific stimuli

that represent such threats to homeostasis. While earlier conceptual models used the term “stress” to encompass any challenge, recent perspectives suggest that the term be restricted to situations that exceed an organism’s regulatory capacity (Koolhaas et al. 2011). Adaptations to specific stressors involve physiological and behavioral changes that are supported by coordinated activity of the nervous and endocrine systems.

## Introduction: The Stress System

Homeostasis involves maintenance of a complex, dynamic equilibrium within the body. Stressors represent challenges to homeostatic regulation, and the brain constantly adjusts behavioral and physiological activity to meet demands of both current and anticipated stress (Ulrich-Lai and Herman 2009). The physiological stress response, involving coordinated activity of the nervous and endocrine systems, is regulated by brain areas that constantly monitor changes in the internal state of the body as well as anticipatory cues in the environment.

Endocrine stress responses are initiated by a cascade of events comprising the hypothalamic-pituitary-adrenal (HPA) axis (Tsigos and Chrousos 2002). Internal (systemic) or external stressors trigger release of corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP) from parvocellular neurosecretory cells in the hypothalamus. CRH, with a potentiating effect of AVP, triggers release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland. ACTH, in turn, stimulates release of glucocorticoids from the cortex of the adrenal gland. The primary glucocorticoid is cortisol in humans and corticosterone in rodents. Glucocorticoids operate at multiple levels to redirect energy resources in the body and to contain the immune response.

Nervous stress responses are mediated in the brain by the locus coeruleus-norepinephrine system (Tsigos and Chrousos 2002). Release of norepinephrine by the locus coeruleus to multiple brain areas causes increased activation of the sympatho-adreno-medullary (SAM) axis.

Activation of this system provides an immediate response to stress and involves sympathetic nerve signals to smooth muscle, cardiac muscle, and glands. Sympathetic signals to the adrenal medulla additionally trigger release of epinephrine and norepinephrine. Increased sympathetic signaling during the stress response is accompanied by altered signaling (usually reduced) through parasympathetic nerves. Activation of the SAM axis produces a set of responses including increased heart rate and energy availability and increased blood flow to muscles and other organs.

Activities of the HPA and SAM axes are regulated by a central autonomic network of brain areas extending from the brainstem to the forebrain (Carnevali and Sgoifo 2014). Systemic stress elicits nervous, hormonal, and immune signals that feed back to the brain. Based on this feedback, brainstem autonomic centers reflexively signal changes in autonomic and neuroendocrine activity. Stimuli in the external environment, in contrast, signal the occurrence of behaviorally relevant events that elicit stress responses. These external stimuli include direct, or neurogenic, stressors such as restraint as well as anticipatory cues in the environment.

Intermittent stressors evoke short-term activation of the stress system. Once activated, several mechanisms promote termination of the autonomic and neuroendocrine stress responses. Cardiovascular recovery following stress-induced autonomic activation is mediated by engagement of a vagal parasympathetic reflex, termed vagal rebound (Mezzacappa et al. 2001). Inhibition of cortisol release in response to short-term stressors is mediated by feedback mechanisms at the level of the paraventricular nucleus of the hypothalamus and the pituitary gland.

## Processing of Systemic Stress

Systemic stressors reflect changes in the internal state of the body. These changes generate nociceptive (pain) signals, neuronal and circulating homeostatic signals, and circulating inflammatory signals (Herman et al. 2003) that are detected by the brain. Several interconnected areas of the

medulla oblongata generate reflexive autonomic responses to systemic stressors.

During physical activity, for example, the nucleus of the solitary tract (NST) in the medulla oblongata receives sensory input related to changes including blood pressure, chemical composition of the blood, and nociceptive signals. Based on these inputs, the mammalian NST adjusts ongoing activity of the cardiorespiratory system through connections with other medullary autonomic centers. Sympathetic tone is regulated by neurons in the ventrolateral medulla oblongata that signal preganglionic neurons in the spinal cord. Neurons in two other medullary areas, the nucleus ambiguus and the dorsal motor nucleus of the vagus, are involved in parasympathetic control. (Ulrich-Lai and Herman 2009).

The NST also relays systemic input to higher brainstem and forebrain areas where they are integrated with descending limbic information. One of these areas, the hypothalamus, is a major center for coordinated control of the nervous and endocrine systems. The paraventricular nucleus (PVN) receives a variety of nervous, hormonal, and immune-related inputs and, on the basis of these signals, adjusts ongoing autonomic activity through connections with pre-autonomic neurons in the brainstem and spinal cord. Based on these inputs, the PVN also increases activity of the HPA through release of CRH. Studies with rodents have revealed that ascending homeostatic signals (such as hunger or pain) are processed in the PVN together with descending limbic signals (such as exposure to a novel environment) evoked by anticipatory stressors. The integrated sum of this processing results in modulation of HPA activity.

## Processing of Neurogenic and Anticipatory Stress

As opposed to reflexive responses discussed above, stress responses to environmental stimuli involve higher-order sensory processing. Laboratory studies in rodents have employed a variety of external stressors to investigate physiological aspects of the stress response; these include restraint, social defeat, and forced

swim paradigms. In these studies, different types of stressors elicit responses in reaction to, or in anticipation of, stressful events. Controllability of a stressor is a key factor in the pattern of physiological stress response. Uncontrollable stressors are associated with delayed physiological recovery in cardiovascular and glucocorticoid measures.

The locus coeruleus (LC) in the pons displays stress-related activation through inputs from central autonomic centers including the paraventricular nucleus (PVN) and the amygdala (Berridge and Waterhouse 2003). Based on these inputs, LC neurons release norepinephrine to areas of the central autonomic network in support of physiological and behavioral stress responses. In addition, the LC plays a role in vigilance and general arousal through extensive connections with other brain areas.

Anticipatory stress responses are regulated by limbic areas in the forebrain and brainstem involved in processing emotion and memory (McDougall et al. 2005). The amygdala, located in the temporal lobe of the cerebrum, generates immediate fear responses involving behavior as well as changes in physiological state through activation of SMA and HPA axes. The central amygdala integrates systemic stressors with environmental, or psychogenic, stress signals from the basolateral and medial amygdala. In rodents, neurons in the basolateral amygdala display activation in response to stressors including predator exposure, footshock, and restraint.

As the major output hub, the central amygdala elicits sympathetic responses through connections with downstream components of the central autonomic control network, including the locus coeruleus, dorsomedial nucleus of the hypothalamus, and nucleus of the solitary tract. The central nucleus of the amygdala activates the HPA axis through connections with the paraventricular nucleus of the hypothalamus.

The bed nucleus of the stria terminalis (BNST), in the basal forebrain, plays a broad role in valence surveillance related to current physical and social context (Lebow and Chen 2016). The BNST provides for coordination of physiological and behavioral responses and adaptive regulation of energy

balance. This area integrates input related to threat and reward with information related to current homeostatic state and arousal. With respect to anticipatory stress, the BNST integrates excitatory and inhibitory input from diverse limbic areas including the amygdala, hippocampus, and medial prefrontal cortex. In contrast to the amygdala, the BNST mediates sustained fear characterizing anxious states. Integrated output from the BNST projects to hypothalamic and brainstem areas involved in ongoing control of autonomic and neuroendocrine activity.

The paraventricular nucleus of the hypothalamus regulates stress responses through coordinated activity of the autonomic and neuroendocrine systems (Buijs and Van Eden 2000). As discussed above, systemic and environmental stressors trigger HPA axis activity and release of glucocorticoids. Stressors also trigger autonomic responses by pre-autonomic PVN neurons projecting to the brainstem and spinal cord. During exercise, the PVN mediates reflexive cardiovascular and neuroendocrine control based on systemic input from medullary centers, including the NST. Systemic input to the PVN includes peripheral inflammatory signals related to infection. The PVN also generates anticipatory stress responses based on input from the amygdala, prefrontal cortex, and hippocampus. These inputs signal changes related to emotion, reward, and mood.

The dorsomedial hypothalamus (DMH) mediates cardiovascular, neuroendocrine, and behavioral stress responses evoked by exposure to threatening stimuli. For this reason, the DMH is a key component of the “hypothalamic defense area.” The DMH integrates stress signals from several forebrain areas including the amygdala, median preoptic area of the hypothalamus, and medial prefrontal cortex (DiMicco et al. 2002). In rodents, excitatory inputs to the DMH are elicited by a variety of laboratory stress paradigms including conditioned fear, immobilization, and swim stress. On the basis of these inputs, the DMH signals pre-autonomic neurons in the brainstem. The DMH is also involved in regulation of HPA stress responses through communication with the PVN.

## Modulating the Stress Response

Adaptive goal-oriented cognition requires that default physiological responses to threat or uncertainty be inhibited by top-down regulatory signals from the forebrain (Park and Thayer 2014). Emotional responses involving the amygdala and hypothalamus are shaped by inhibitory inputs from the hippocampus and prefrontal cortex. Distinct forms of emotion regulation have been identified that differentially recruit areas of the amygdala, hippocampus, and prefrontal cortex.

Together, the hippocampus and ventromedial prefrontal cortex exert automatic regulatory control over autonomic and neuroendocrine stress responses. While the amygdala and hippocampus are both critical for fear conditioning (Phelps 2004), the hippocampus is specifically involved in recall of the contextual aspects of fear responding. Studies in rodents and humans indicate that the hippocampus is also critical for safety learning and fear extinction, whereby an animal learns that certain contexts are no longer threatening. Recall of fear extinction memory activates both hippocampus and medial prefrontal cortex, and these areas, along with the amygdala, constitute a fear extinction network (Quirk and Mueller 2008). This network is active during consolidation and retrieval of fear extinction memory. Medial prefrontal cortex also directly inhibits HPA and SMA axes through connections with brainstem autonomic areas and the PVN (McKlveen et al. 2015).

In humans, emotional stress responses are also regulated through effortful strategies including suppression and cognitive reappraisal (Goldin et al. 2008). Emotional suppression involves attempting to hide or inhibit ongoing behavior. This strategy recruits ventrolateral prefrontal cortex for behavioral inhibition and is also associated with greater amygdala activation and increased physiological stress responses. Cognitive reappraisal, in contrast, involves reinterpreting the meaning of an emotional situation. Cognitive reappraisal of stressful stimuli evokes activity in lateral prefrontal cortex and ventromedial cortex but reduces activity in the amygdala with associated reduction of autonomic and neuroendocrine stress responses.

## Stress and Neuroplasticity

Chronic stress exposure induces a persistent state of physiological activation referred to as allostasis (McEwen and Gianaros 2011). Such exposure can lead to long-term changes in the structure and function of brain areas involved in the stress response. This capacity for change in synaptic organization, termed neuroplasticity, encompasses a variety of adaptations that either depress or facilitate synaptic activity (Bains et al. 2015). Neuroplasticity permits information storage related to prior experience and allows the brain to shape subsequent responses to stress. Maladaptive neuroplasticity impairs stress regulation and is associated with deficits in cognition and mood disorders. Exposure to chronic or intense psychological stressors may increase the response to subsequent stress. Adaptive neuroplasticity, in contrast, enhances regulation of stress responses and is linked to improvements in cognition and memory. Systemic stress related to repetitive physical activity triggers adaptive neuroplastic changes that reduce the impact of psychological stress.

Central autonomic circuits that process systemic stressors overlap with those involved in processing psychological stressors. Thus, neural adaptations to a particular stressor can modulate reactivity to stressors of a different modality (Rimmele et al. 2009). This effect is the key to how physical activity reduces the physiological impact of psychological stress.

## Psychological Stress and Maladaptive Neuroplasticity

Chronic or intense psychological stress can impair the capacity for emotion regulation and has negative effects on memory and cognition. Recent research suggests that these effects are due to maladaptive neuroplastic changes in stress regulatory areas including the amygdala, hippocampus, and medial prefrontal cortex. Chronic psychological stress increases the size of the amygdala with associated changes in dendritic structure (Pittenger and Duman 2008). The resulting increases in amygdala activity may enhance fear learning and anxiety.

In contrast to the amygdala, chronic stress induces decreased size and activity of the hippocampus and medial prefrontal cortex. These effects are mediated by excessive exposure to stress-induced neurotransmitters and glucocorticoids. Rodent studies have linked acute and chronic stress exposure to suppression of neurogenesis, dendritic atrophy, and impaired memory formation in the hippocampus. Chronic stress also decreases dendritic density in the medial prefrontal cortex. These effects help explain the effects of stress on the development of mood disorders as impaired hippocampal neurogenesis is a key neural correlate in major depression (Pittenger and Duman 2008). Deficits in emotion regulatory capacity are reflected in indices of peripheral autonomic control. Psychopathologies such as anxiety and depression, for example, are characterized by lower measures of heart rate variability (Park and Thayer 2014).

Chronic stress alters HPA axis regulation by the paraventricular nucleus in complex ways, depending upon the nature and duration of the stressor. Chronic stress initially triggers increased expression of CRH and output of glucocorticoids. Physiological effects of excessive cortisol output include visceral adiposity, insulin resistance, and psychological disorders including anxiety and depression (Tsigos and Chrousos 2002). With exposure to longer-term or severe stressors, however, cortisol output is reduced. Moreover, reduced expression of receptors may lead to glucocorticoid resistance and detrimental effects on immune function.

## Physical Activity and Adaptive Neuroplasticity: Brainstem and Hypothalamus

Regular physical activity evokes neuroplastic changes in the brainstem and hypothalamus. Mechanisms of neuroplasticity in these areas include increased vascularization, synaptic modification, and long-term changes in gene expression (Voss et al. 2013). Studies in rodents link regular exercise to altered neurotransmission in the brainstem and to dendritic changes in multiple brainstem areas involved in cardiovascular

control. Beneficial effects of exercise-induced neuroplasticity include (1) optimization of autonomic activity at rest and during exercise and (2) reducing the physiological impact of psychological stress.

In response to regular exercise, neurons in the rostral ventrolateral medulla and NST display alterations in signaling by the neurotransmitters GABA and glutamate, leading to decreased sympathetic and increased parasympathetic signaling (Martins-Pinge 2011). In rodent studies, other effects of regular exercise include reduction in dendritic density in the NTS and periaqueductal gray matter, reducing the relative number of excitatory synapses and decreasing resting sympathetic tone and reactivity. Exercise-induced effects on medullary areas, including the NST, are also linked to oxytocin released from the PVN (Micheline and Stern 2009). Oxytocin exposure may serve to enhance vagal outflow signals from the brainstem, thus moderating heart rate responses to exercise. Neuroplastic changes in other areas of the medulla oblongata are linked to production of peripheral signaling molecules. Irisin, a circulating myokine produced by muscle cells, evokes synaptic adaptations in cardiac-projecting neurons of the nucleus ambiguus in the medulla oblongata (Brailoiu et al. 2015) and increases parasympathetic outflow through the vagus nerve.

Chronic exercise also alters GABA signaling in the PVN of the hypothalamus, with corresponding reductions in sympathetic tone and blood pressure. In rodents, neuroplastic changes in the PVN also alter HPA activity with reductions in glucocorticoid levels and reduced reactivity to psychological stressors (Morgan et al. 2015). Exercise-related homeostatic signals in the PVN linked to neuroplastic changes include blood glucose and nitric oxide.

### **Physical Activity and Adaptive Neuroplasticity: Hippocampus and Amygdala**

Physical activity triggers neuroplastic changes in limbic forebrain areas, with the most pronounced effects observed in the hippocampus and amygdala.

Exercise promotes hippocampal neurogenesis, changes in dendritic morphology, and long-term potentiation with corresponding improvements in spatial learning and memory tasks (Vivar et al. 2013). Regular exercise also reduces age- and disease-related declines in neurogenesis.

Regular physical activity promotes adaptive neuroplastic changes in the hippocampus by stimulating central and peripheral production of key signaling molecules (Cotman et al. 2007). These include insulin-like growth factor 1 (IGF-1), brain-derived neurotrophic factor (BDNF), and vascular endothelial growth factor (VEGF). BDNF is the most widely expressed neurotrophin, and exercise increases levels of BDNF in several areas of the brain including hippocampus and amygdala. Rodent studies suggest that exercise-related increases in hippocampal BDNF are mediated in part by peripheral signaling molecules including IGF-1, ghrelin, and irisin. Chronic exercise may support the effect of IGF-1 on adaptive neuroplasticity by decreasing the production of pro-inflammatory cytokines.

Physical activity also evokes adaptive neuroplastic changes in the amygdala. These effects are mediated in part by increased expression of BDNF and other molecules in the basolateral amygdala involved in intracellular signaling and synaptic function (Liu et al. 2009).

Effects of exercise on the amygdala are dependent upon the nature and intensity of the activity. Chronic treadmill running, but not wheel running, in rodents increases levels of BDNF in the amygdala associated with improvements in cued fear learning.

Regular exercise, by stimulating BDNF production in the amygdala, may promote proper regulation of amygdala function by serotonin (Daftary et al. 2012). Experimental depletion of BDNF in the amygdala of mice reduces the inhibitory effect of serotonin, increasing stress-related signaling by the amygdala. Moreover, exercise-induced changes in serotonergic signaling in the dorsal raphe nucleus of the midbrain may reduce stress signaling to the amygdala, thereby enhancing resilience to external stressors (Morgan et al. 2015). Treadmill and wheel-running paradigms in rodents increase expression of a regulatory protein, galanin, in the locus coeruleus. The resulting

reduction in noradrenergic signals to the amygdala limits anxiety and improves fear conditioning.

## Effects of Physical Activity on Mood and Cognitive Performance

Adaptive neuroplasticity provides the capacity to shape brain responses to ongoing systemic and environmental challenge. Neuroplastic modifications prevent excessive activation of the stress system and permit more efficient energy allocation. Exercise-induced changes in the hippocampus reduce the impact of psychological stress by providing contextual safety signals to other parts of the brain, such as the hypothalamus, involved in stress system activation (Buijs and Van Eden 2000). Neuroplastic changes in circuits involving the amygdala reduce excessive stress system activation in response to perceived threat.

In humans, neuroplastic changes contribute to antidepressant and anxiolytic effects of regular physical activity. Activity-induced neuroplasticity enhances cognitive function by facilitating emotion regulation and the ability to flexibly engage coping mechanisms. By reducing the impact of psychological stress, regular exercise promotes adaptive structural changes in the parts of the brain involved in memory, cognition, and emotion regulation (McEwen and Gianaros 2011).

In rodents, regular exposure to physical activity and enriched environments promote adaptive neuroplastic changes, but through distinct pathways (Olson et al. 2006). Evolutionarily, both conditions may signal a need for adaptation to environmental complexity. Seen in this context, hippocampal neurogenesis represents an investment in future capacity for learning in similar environments. Hippocampal neurogenesis in mammals may also facilitate behavioral modifications during maturation.

## String Pulling

Ivo Jacobs

Department of Cognitive Science, Lund  
University, Lund, Sweden

### Definition

Retrieving an out-of-reach object by pulling a string attached to it.

### Introduction

During a cold Swedish winter, a raven watches a fisherman cut a small hole in a frozen lake. He drops in a baited fishing line attached to a stick to secure it over the hole. After he leaves, the raven flies down and examines the situation. Although she cannot see deep down the dark waters, she takes the line in her beak, pulls it, and steps on the loop. Repeating this sequence several times, she eventually reaches the end and eats the bait. Other ravens observe how she got her easy catch and make their own attempts with the numerous ice-fishing holes in the country's largest lake. By the end of the winter, local fishermen have stopped ice fishing because they nearly always return home empty-handed due to the ravens' efficient pilfering (Larsson 1958).

These ravens exhibited spontaneous string pulling: they retrieved out-of-reach food (bait and fish) by pulling a string (fishing line) attached to it. String pulling is one of the oldest and most common tests of animal cognition. The Roman naturalist Pliny the Elder (23–79 AD) first documented how goldfinches pull up strings with food and containers of water. Since the beginning of the twentieth century, researchers have investigated the cognitive abilities of a wide array of species by using various string-pulling tests. Around 170 species have been tested in over 210 studies, with these numbers rising rapidly (Jacobs 2017; Jacobs and Osvath 2015).

## Cognition and String Patterns

String pulling provides countless testing conditions when the number and patterns of strings are varied. The simplest configuration is a single straight string that can be pulled to retrieve the attached out-of-reach reward. Its orientation strongly influences performance; horizontal strings are typically easier to pull than vertical ones. Vertical string pulling requires better coordination and motor planning, involving multiple steps of grasping, pulling, and securing the string, with gravity pulling the string back to its original position if a mistake is made. In contrast, horizontal strings require fewer and easier steps and stay in position when pulling has stopped. Most animals therefore perform better on horizontal than vertical setups. For example, human and gorilla infants can pull horizontal strings at an earlier age than vertical ones (Redshaw 1978). Different test orientations hinder species comparisons, with mammals typically tested on horizontal tasks and birds on vertical ones.

Although a single string is the most common condition, it is unclear what cognitive abilities underpin a successful response. String pulling is often seen as a test for means-end understanding, which involves the deliberate execution of a sequence of steps and the removal of an obstacle to achieve a goal (Huber and Gajdon 2006). However, other mechanisms, such as play behavior, and associative learning can also explain successful string pulling. For example, some animals play with strings and may accidentally pull in baited strings as part of their play behavior rather than due to a deliberate attempt to retrieve the food. This alternative interpretation can be avoided by allowing the animal to interact with unbaited strings before testing begins, so they habituate to the string prior to testing. It is also possible to succeed on string-pulling tasks through associative learning. Touching the string may cause the reward to move, which can lead to an association between both events and eventually successful pulling through trial and error. The reward immediately moves closer with every pull, which can form a positive association leading the animal to repeat whatever behavior caused

it. Consequentially, experienced animals may pull strings indiscriminately. For example, after pulling up a string and removing the food, some rats pull up the same string again only to find there is nothing attached to it (Ewer 1971).

Animals should be tested on multiple conditions to reveal the cognitive mechanisms they employ during string pulling. In the *parallel* condition, an unbaited string is placed parallel to the baited one (see Fig. 1). Goal directness is shown when animals repeatedly pull the baited instead of the unbaited string. If they only pull strings accidentally, through play, or without attention to the reward, they would pull both equally. For example, a common myna did not perform above chance on the parallel condition in over a thousand trials, and neither did a young jackdaw in over 500 trials, possibly because they were too inattentive and playful (Dücker and Rensch 1977). The *converging* condition requires animals to attend more to the orientation of both strings (see Fig. 1). Nonetheless, a successful strategy in both conditions is to use reward proximity as a cue for which string to pull. The *slanted* condition can show the presence of this heuristic (see Fig. 1). When the baited string slants toward the outside of the pattern, pulling the end of a string closest to the reward will still be successful. In contrast,

when the baited string slants toward the inside, reliance on the proximity of the reward will result in failure. This proximity error is common in many species, with dogs being an especially susceptible example (Osthaus et al. 2005). When the strings are *crossed* (see Fig. 1), reliance on proximity always leads to failure. This may explain why animals typically perform worst on the crossed condition.

Myriad variations of string patterns of various complexities are possible. The *pseudo-crossed* and *double crossed* patterns (see Fig. 1) are meant to increase complexity by introducing non-linear strings, but success on these conditions does not necessarily imply visually tracing the strings; here, too, animals may simply rely on the proximity of the reward (Jacobs and Osvalth 2015). Two rewards are present in the *contact* condition (see Fig. 1), but only the correct one is attached to a continuous string, while the other reward is attached to a string with a gap. The proximity error is then revealed when animals pull both strings indiscriminately.

Means-end understanding excludes heuristic strategies such as using the proximity of reward as a cue for which string to pull. Nonetheless, attending to proximity can sometimes be beneficial. In the *proximity* condition, two functional

**String Pulling, Fig. 1** Twelve common string-pulling conditions (patterns). These examples are horizontal, and most also work vertically. The correct string is always shown on the left, but the position of the baited string is typically counterbalanced across sides. This can make a large difference in the *slanted* condition, because it is asymmetrical and can show the proximity error when the baited string slants to the inside, as shown here. In the

*proximity* condition, both strings can be pulled to retrieve the reward, but the string with the closest reward is the optimal choice. The top row shows the six most common traditional patterns, always having only one reward present. The bottom row shows more recent adaptations with two rewards, which ensures subjects cannot use the position of the reward alone as a cue to which string to pull

baited strings are present, so either can be pulled to retrieve a reward, but pulling the string with the closest reward is the optimal response (see Fig. 1). This kind of efficiency is exhibited by some ravens that attend to object identity (food or not) and proximity simultaneously (Pfuhl 2012).

In the *overload* condition (see Fig. 1), both parallel strings are baited, but one reward is too heavy for the animal to pull in. Under typical circumstances, the subject first approaches the large reward due to its saliency. If he is capable of knowing he cannot pull in a large reward, he should only pull the string attached to the smaller reward. Most ravens ignore overloaded strings without trying to pull them even once (Heinrich 1995; Pfuhl 2012). Such behavioral flexibility is another component of means-end understanding.

Animals go beyond superficial perceptual cues through functional generalization and affordance learning. Recognizing the functional aspects of string pulling allows for successful transfer between conditions. Moreover, changes to the strings' color, texture, or material will then not affect performance. This is indeed not a significant challenge for most species tested after such changes (Jacobs and Osvath 2015). Functional generalization is also evident when individuals use different pulling techniques, which shows they do not have stereotyped responses to similar situations. This can best be investigated with vertical strings, which some animals, particularly birds, may pull in diverse manners. Up to eight different techniques have been reported in kea (Werdenich and Huber 2006).

Most patterns involve straight strings that will immediately bring the reward closer when pulled. Approaching food is rewarding and can therefore create a positive association that leads to repeated pulling without means-end understanding. Unbaited strings are then not repeatedly pulled because they are not reinforced with food moving closer. The effects of visual feedback, or absence thereof, is tested with nonlinear strings. The *coiled* condition involves two coiled strings such that pulling one does not immediately cause its distal end to move (see Fig. 1). As in the *contact* condition, a reward is present next to the broken strings to control for strategies based on reward location. Some

Neotropical parrots chose the connected coiled string above chance, but their previous experience with other patterns may have influenced their choices (Schuck-Paim et al. 2009). In the *looped* condition, the strings loop around a solid object, which when pulled causes its distal end to move away at first (see Fig. 1). An olive baboon appeared to prefer the correct looped string (Bolwig 1962), but this condition has not been tested recently or reliably (Jacobs and Osvath 2015).

Animals relying solely on the reward moving closer would therefore not succeed in these conditions. Visual feedback is also minimized when a straight string is attached to a reward that cannot be seen at first. Ice-fishing ravens exemplify this; it is initially impossible to see the bait or fish when the fishing lines are long and the water is dark. Similar setups are possible for other modes of feedback, such as the weight of closed containers at the string's end (Klüver 1961).

Some authors consider successful string pulling to show means-end understanding, but this is not necessary in all cases. Animals show means-end understanding if (1) they are goal-directed, as tested with the *parallel* condition; (2) they do not rely on reward proximity, as tested with the *slanted*, *crossed*, and *contact* conditions; (3) they can functionally generalize, as shown by overall behavioral flexibility or tested with the *overload* condition and changes to nonfunctional elements of other conditions; and (4) they do not rely strongly on perceptual feedback, as tested with the *coiled* and *looped* conditions (Jacobs and Osvath 2015).

Understanding strings as means to retrieve out-of-reach goals does not guarantee success on all conditions. For instance, it does not necessarily involve an understanding of connectedness. In addition to revealing proximity errors, the *contact* condition tests for the ability to recognize the necessity of contact between string and reward. This is more challenging than the *parallel* condition for many species, such as galahs and cockatiels (Krasheninnikova 2013). However, it is also possible that animals prefer continuous surfaces or generalize from previous conditions in which the baited string always looked similar: continuous and contacting the reward. They may simply

disregard the incorrect option or only consider it as an unbaited piece of string.

In the *connection* condition (see Fig. 1), the distal end of the “broken” string lies against its proximal end, so no gap is visible. Recognizing contact as a relevant property does not suffice here; it requires knowledge of the necessity of a structural connection between string and reward. Chimpanzees appeared unable to distinguish between these possibilities (Povinelli 2000). When animals perform better on the *contact* than *connection* condition, it is likely because they consider contact to be a sufficient and necessary mechanism. They may also try to move away with the reward still attached to the string connected to the substrate. For example, some ravens and American crows tried to fly off with food attached to a string tied to a perch, resulting in them being yanked back unless they dropped the food first (Heinrich 1995).

A controversial cognitive mechanism often associated with string pulling is insight. Definitions vary but often revolve around suddenly arriving at a solution by recombining previous experiences. How different amounts and types of experience influence problem-solving abilities is a contentious issue central to the string-pulling paradigm (Jacobs and Osvath 2015). Performance often improves within conditions and may depend on previous experience on different conditions. For instance, juvenile rhesus macaques perform worse on the *pseudo-crossed* condition when having previous experience on the *crossed* condition compared to the *parallel* condition (Mason and Harlow 1961). This suggests they transferred their previous experience based on proximity.

Heinrich (1995, p. 1001) tested ravens on vertical string pulling and proposed four explanations for spontaneous success: “(1) random chance; (2) programming already present at birth; (3) learning both the sequence and its effects; (4) insight associated with or without some or all of the above.” He considered chance an unlikely explanation for immediate execution of the different action sequences. Neither did he regard genetic programming likely because little or no behavior in the wild corresponds to it. He acknowledged that the ravens might have learned

some aspects of the tasks but that this does not explain their spontaneous solution of several conditions. He therefore concluded that insight is the most plausible explanation.

However, there are plausible alternatives to these explanations, as already discussed above. Possibly the most convincing case of insightful string pulling would be an immediate solution to the *crossed* condition after an initial impasse without any previous string-pulling experience and not resulting from chance, trial and error, visual feedback, or innate processes (Jacobs and Osvath 2015). This has so far not been shown in any species because some factors, such as chance and rapid trial and error, cannot be excluded in the first trial. Insight remains a vague concept that is more informative when deconstructed into its fundamental cognitive abilities that can be investigated independently (Shettleworth 2012).

## Ecology and Evolution

The cognitive abilities required for successful string pulling may benefit animals in their natural environments. Numerous reports have documented how several species pull stringlike objects to retrieve attached food. For instance, olive baboons pull up the nests of weaverbirds to take their eggs (Laidre 2008), Eurasian jays pull up oak seedlings to retrieve buried acorns (Bossema 1979), tufted titmice pull up caterpillars hanging from branches by their threads (Dickinson 1969), and orangutans obtain 61% of their plant intake by pulling branches to reach leaves and fruits (Chevalier-Skolnikoff 1983). Therefore, this behavior may be facilitated, in some cases, by a species’ natural ecology.

Some authors argue that such ecological parallels reduce the cognitive abilities required for string pulling (e.g., Altevogt 1954). Genetic programming could result in functional means-end behavior without complex cognition. Some adaptations are beneficial for string pulling, whether originally selected for these behaviors or not. There is suggestive evidence that playfulness, attentiveness, visual acuity, and manipulation

skills increase the string-pulling performance of primates (Harris and Meyer 1971; Jolly 1964). In birds, one of the most important species-specific factors is the use of feet in feeding. Birds that do not use their feet for holding food generally fail to anchor pulled-up vertical strings under their feet and therefore cannot retrieve the reward. They perform markedly better on horizontal string pulling since it does not require stepping on the string (Jacobs and Osvath 2015).

Ice-fishing ravens illustrate these issues. While it shows string-pulling behavior in the wild, countering Heinrich's (1995) argument that little to no such behavior exists under natural circumstances, it is unlikely ravens specifically adapted to ice fishing since it is a regional tradition that humans have been practicing for a time period that is very brief in evolutionary terms. Moreover, ravens improve with experience, differ individually in pulling technique, and are initially neophobic toward food suspended on strings (Heinrich 1995). Genetic programming for string pulling is therefore unlikely. Conversely, ravens frequently use their feet in feeding, which is more likely to have been directly selected genetically. Individuals innovate how to perform multi-step string-pulling sequences, which benefits from sensorimotor skills adapted for other reasons, such as holding food (Jacobs 2017). Future studies should investigate how wild ravens learn to pull up unattended fishing lines and how this behavior spreads through the population.

Since string-pulling tests are easy to administer, they are often used as indicators of general cognitive abilities in studies on ecology and evolution. For instance, 25% of wild great tits tested on vertical string pulling obtained the food within an hour. Their performance was stable over years, independent of various factors such as sex, neophobia, and body condition, and correlated with performance on another operant task (Cole et al. 2011). Females that performed better laid larger clutches but were also more likely to abandon their nests, showing a trade-off in fitness value for the cognitive abilities associated with string pulling (Cole et al. 2012). Large-scale studies on problem-solving abilities in wild species with controls on many variables are unfortunately

rare. The string-pulling paradigm offers a relatively easy tool that is suitable for such purposes.

Until recently, only mammals and birds have done string-pulling tests. Alem et al. (2016) investigated string pulling in bumblebees and found that 2 out of 135 subjects spontaneously pulled a single horizontal string within 10 min, possibly through their persistence, exploration, trial-and-error learning, or sheer luck. Others learned to do so through social learning, resulting in the behavior slowly spreading throughout the colony. Three out of eight successful bumblebees also passed the *coiled* condition, but none of the 27 observing bees pulled in a coiled string completely. The authors concluded that observing bumblebees are attracted to the demonstrator's location and the position of the string and that carrying out the pulling sequence relies on trial and error mediated by perceptual feedback of the reward moving closer. Thus, associative mechanisms and trial and error appear to explain string-pulling behavior in bumblebees, not means-end understanding or insight. This study illustrates the requirement of multiple testing conditions to distinguish between alternative explanations and yield conclusive results.

Species comparisons are difficult because many factors may influence string-pulling abilities, and these can obscure intra- and interspecific cognitive differences. With increased awareness of these issues and better study designs to accommodate or control for them, some meaningful comparisons are possible. Most tested animals have successfully pulled in single baited strings. As already discussed, the cognitive abilities required for this behavior are often unclear and less sophisticated than typically assumed, but it shows which species have the required sensorimotor capacities and are therefore suitable for further testing. Although around 170 species have been tested on the string-pulling paradigm, most of them are primates, carnivores, passerines, and parrots, which limits the scope of phylogenetic analyses (for the most recent phylogeny of string-pulling species, see Jacobs 2017).

Even in primates, not enough studies have been done with comparable methods or multiple species to allow for larger comparisons. However,

one meta-analysis ranked species performances across several studies and showed that apes generally outperform monkeys on string-pulling tasks (Deaner et al. 2006). This parallels findings on numerous other tasks, which likely reflects differences in brain anatomy and socio-ecology between apes and monkeys. String pulling is highly suitable for phylogenetic comparative psychology because it involves minimal training, relatively few trials per subject, and the ability to easily adapt materials and testing protocols for different species (MacLean et al. 2012). However, a large-scale comparative phylogenetic study of string pulling does not exist yet. While the total number of studies is very large for this field, they have a limited phylogenetic scope. To better reconstruct the evolution of the cognitive skills underlying this ability, some uncommon taxa should be tested, such as monotremes, marsupials, and paleognaths. This will increase the phylogenetic breadth significantly more than additional studies on common taxa such as primates and passerines. With the discovery of string pulling in bumblebees, researchers should be encouraged to investigate species outside the mammal and bird clades.

## Conclusion

String pulling has a rich history and promising future. The variety in experiments conducted, species tested, and explanations offered attests to its broad utility in animal cognition and behavior. However, strong conclusions should not be made without exploring possible confounding factors and administering several conditions due to the many different cognitive mechanisms that may underlie string pulling. Nearly endless patterns are possible to this end. When investigating different cognitive abilities, the patterns in Fig. 1 may be most useful, especially the *parallel*, *slanted*, *crossed*, *overload*, *contact*, *connection*, and *coiled* conditions. Considerate use of the string-pulling paradigm will likely prove to be invaluable in the study of various cognitive abilities, including their relationships to ecology and evolution, throughout the animal kingdom.

## Stroop Effect

J. Antonio Salamanca<sup>2</sup> and David A. Washburn<sup>1,2</sup>  
<sup>1</sup>Covenant College, Lookout Mountain, GA, USA  
<sup>2</sup>Georgia State University, Atlanta, GA, USA

## Definition

The Stroop task and its corresponding effect are among the best known, most frequently researched phenomena in cognitive psychology (MacLeod 1991; Washburn 2016). In its most recognizable form, participants are required to indicate, as quickly as possible, the print color of a series of words, some of which are themselves incompatible color words. J. Ridley Stroop (1935) studied interference in color naming by comparing performance in baseline conditions to a condition in which the color stimuli were themselves incongruent color words (e.g., the word GREEN printed in red, the word BLUE printed in yellow, and so forth, where the corresponding correct response would be “red, yellow, . . .”). This interference, manifest as slower responding and increased errors, has become known as “the Stroop effect” and was originally interpreted as reflecting the difference in response strength between the conflicting stimulus dimensions. Each word itself has a single, strongly associated response: the word’s meaning (e.g., the letters

BROWN become strongly associated with the response of reading the word “brown”), whereas colors have multiple associated responses (e.g., the color *brown* may be associated with responses connected to dirt and chocolate and wood and many other brown things). Thus, the defining characteristic of the Stroop task in its classic form is the conflict between a relatively weak to-be-named feature of a stimulus and the prepotent but incongruent meaning of that stimulus.

In the eight decades since Stroop’s (1935) original report, there have been more than 6000 publications that replicated, extended, or otherwise referenced the Stroop task and/or effect. In truth, however, relatively few of these studies employed J. Ridley Stroop’s original procedure. Whereas the color-naming task remains the standard, Stroop-like interference has also been reported using dozens of variations, in which stimulus dimensions other than color are pitted in competition for behavior (see reviews by MacLeod 1991, 1992). This fact provides an important first disclaimer for the present discussion of Stroop-task studies in the comparative-cognition literature, as no nonhuman animal has to date been (and it is unlikely that any could be) tested on Stroop’s original procedure that required reading verbal stimuli and vocal responding; however, many of these Stroop-like task variations are amenable to cross-species comparison. Note consequently that the term *Stroop effect* is generally reserved for interference between word-meaning and word-color, loosely following the original Stroop (1935) contrast, whereas interference between stimulus meaning (e.g., the value of an Arabic numeral) and some other stimulus dimension (e.g., the physical size of an Arabic numeral; Besner and Coltheart 1979) is typically termed a *Stroop-like effect*.

As a second disclaimer, it must be acknowledged that there are also many tests other than the Stroop task that present conflict between a prepotent response and a target response. For example, the Attention Network Task (ANT; Fan et al. 2002) measures interference between a stimulus and incongruent flanking stimuli (e.g., an arrow, surrounded by arrows pointing in the opposite direction) to assess executive attention. The

Simon effect (e.g., Simon and Berbaum 1990) reflects conflict between a stimulus and its spatial position. Within the animal-learning literature, there is a long and productive history of placing conditioned stimuli in conflict with one another. For example, Ray (1969) separately trained rhesus monkeys (*Macaca mulatta*) to respond to color stimuli and to line-orientation cues and then combined the stimuli so as to examine the effects of conflicting compound stimuli on attention and behavior. Much of what is known about phenomena like blocking, overshadowing, and similar selective-attention effects was determined from experimental investigations of the stimulus-control of the behavior of rats, pigeons, and other nonhuman animals under conditions of competing discriminative cues (for reviews of this literature, see Rosas et al. 2017, Zentall 2005). These cue-competition paradigms are clearly related to the present topic but are not typically considered to be *Stroop(-like)* and in general will not be discussed further in this review.

However, Lauwereyns and collaborators (2000) reported interference described as “a behavioral analogue of the human Stroop effect” (pg. 352) from such a test of cue conflict within compound discriminative stimuli. Japanese macaques (*Macaca fuscata*) were trained on separate stimulus-color, stimulus-shape, and stimulus-movement discriminations in a go/no-go paradigm. These animals were subsequently shown to respond more slowly and to produce more errors when incongruent color/shape/movement cues were combined (e.g., a stimulus in the “go” color but in the “no-go” shape). The authors further reported that the effects of irrelevant but incongruent stimulus cues were cumulative, such that a “go” stimulus with two “no-go” features produced more interference than if only one “no-go” feature was present. This finding of cumulative interference is interesting and potentially useful for further examination of individual and group (including species) differences in the magnitude of Stroop-like interference and the attention-control mechanisms that underlie it. However, the paper also highlights the impossibility of drawing a clear categorical boundary

(on a basis other than the researchers' choice of terms) between cue-competition findings that should "count" as Stroop-like effects and those that do not.

## Stroop Effects for Color Symbols

In the closest analogue to the original Stroop task performed by a nonhuman animal to date, Beran et al. (2007) leveraged the unique symbolic-communication competencies of a chimpanzee (*Pan troglodytes*) named Lana to test her on a color-naming task. Beginning in 1972, Lana was trained to use a computerized keyboard that featured visuographic symbols called *lexigrams* (Rumbaugh 1977). Each lexigram corresponded to a word, and Lana was trained to produce sentences by combining symbols in accordance with a novel grammar (e.g., Rumbaugh 1977, Rumbaugh and Washburn 2003). Lana learned to use the keyboard to make requests, to label objects, to comment on events, to respond to questions, and so forth. She also understood and responded appropriately to keyboard-based communications by human experimenters or caregivers. The lexigrams primarily represented nouns and verbs, but Lana was also taught some adjectives – including some colors. Because Lana remembered her symbol meanings for decades (Beran and Heimbauer 2015), Beran and collaborators were able to test this chimpanzee on a color-naming task that almost exactly reproduced the Stroop task commonly used with human participants.

For this experiment's training phase, Lana was required correctly to categorize colored clip-art stimuli as blue or yellow using "B" and "Y" response options on a computer screen (Beran et al. 2007). When she met the training criterion, Lana was advanced to the testing phase of the study. On each trial of this phase, Lana saw one of eight possible stimuli, including the lexigram symbols that stood for the colors blue and yellow. These lexigrams could be presented as congruent stimuli (i.e., the blue lexigram colored blue, the yellow lexigram colored yellow) or as incongruent stimuli (i.e., the blue lexigram colored yellow,

the yellow lexigram colored blue). Lana showed significantly lower accuracy on incongruent trials when compared to training or control trials (i.e., trials with arbitrary stimuli colored blue or yellow) or the congruent-lexigram trials. This effect is similar to what is typically observed for human adults and children when they show differences in accuracy on the Stroop task; however, whereas human adults and children typically show Stroop effects in response-time measures, Lana did not take more time to respond to incongruent trials.

These findings might suggest a qualitative difference between Stroop effects of nonhuman versus human primates; however, a recent study in which a task like Lana's was administered to rhesus monkeys (*Macaca mulatta*) belies this suggestion. Using a symbolic matching-to-sample paradigm, Callery et al. (2015) trained macaques on the meanings of four color symbols. On some trials, the monkeys saw one of the color symbols on a computer screen. The monkey manipulated a joystick so as to bring a computer-graphic cursor into contact with this sample stimulus, whereupon two clip-art images were presented. These images were identical, except for color. For example, the sample image might be the symbol for RED, and the choice stimuli might be two pictures of umbrellas, identical except that one was red and one was blue. The positions of the choice stimuli were randomized. On other trials, a clip-art image was presented as the sample (e.g., a yellow house), and the choice stimuli were two color symbols (e.g., the symbol for green and the symbol for yellow). Irrespective of trial type, the animals were rewarded for selecting the appropriate symbol-color pair. When a monkey achieved training criterion on all four stimuli, novel clip-art images were introduced to test for generalization.

Following the generalization tests, the monkeys were trained to sort new clip-art stimuli on the basis of color, by manipulating the joystick so as to drag the stimuli into contact with the red, blue, yellow, or green border of the screen. On probe trials, one of the color symbols was presented as the to-be-sorted stimulus. Each symbol appeared either in a congruent color with the symbol's meaning (e.g., the symbol for yellow,

colored yellow) or in an incongruent color (e.g., the symbol for red, colored yellow). In any case, the animal was rewarded for sorting on the basis of stimulus color, irrespective of the identity of the image. The rhesus monkeys produced significantly more sorting errors on incongruent trials than on congruent-symbol or baseline (clip-art) trials. They also responded significantly slowest on the incongruent trials. Although these color symbols were certainly not language-like in the way that is true for Lana's lexigrams or human's words, the monkeys did replicate Lana's Stroop interference (Beran et al. 2007) as well as the interference effects of incongruent trials on human's accuracy and response time.

### Numerical Stroop-Like Effects

The Klein et al. (2017) findings also replicated the effect from the very first known Stroop-like test of nonhuman animals. Two rhesus monkeys that had previously learned the relative numerosness represented by Arabic-numeral symbols (Washburn and Rumbaugh 1991) were tested on a numeric Stroop-like task (Washburn 1994). On each trial of this new task, monkeys were presented with two arrays of letters (e.g., five Cs vs. two As) and were rewarded for moving the cursor into contact with the array with more stimuli. The identity of the stimuli was irrelevant to the task. The monkeys quickly mastered this task, whereupon Stroop-like trials were interspersed into blocks of these baseline trials. On congruent trials, the array with the most stimuli also contained the larger Arabic numeral (e.g., four 3s versus one 2). Incongruent trials presented the larger Arabic numeral in the smaller array (e.g., two 5s versus three 1s). Irrespective of trial type, the monkeys and a group of human participants were simply required to select the larger of the two arrays based on item count, regardless of the stimuli contained in the arrays.

As was previously reported for humans on a numerical Stroop-like test (Besner and Coltheart 1979; for similar reports using other variations on the numerical Stroop paradigm, see Cohen 2009, Wolach et al. 2004), both the rhesus monkey and

human participants demonstrated significant Stroop-like interference in response times (Washburn 1994). Irrespective of species, participants required more time to respond to stimuli when numerical-symbol magnitude was incongruent with relative quantity. Rhesus monkeys were also significantly more prone to error in the incongruent condition when compared to congruent array sets or nonnumerical array sets, in an effect that would anticipate the 2007 finding with Lana chimpanzee (Beran et al. 2007).

The numeric Stroop-like task permitted some additional analyses that are not typical of research with the Stroop color-word variation. Washburn (1994) tested the hypothesis that Stroop-like interference is based on stimulus-response association strength, as had been originally posited by Stroop (1935), by examining how the Stroop-like effect changed as a function of the symbolic distance between the stimuli within a trial. That is, two 3s vs. four 2s are an incongruent trial, but it may not be equally incongruent as two 5s vs. four 1s. Indeed, the magnitude of Stroop-like interference generally increased, both for monkeys and for humans, as the absolute difference between the Arabic numerals in incongruent trials increased – just as would be expected if Stroop interference was based on strength of association. A similar effect was not observed as a function of differences in array size (e.g., the interference on incongruent trials like four 1s vs. two 3s was not significantly different than the interference on trials like six 1s vs. one 3). Washburn (1994) argued that this latter difference would have supported a “speed of processing” explanation for Stroop effects but that the data from monkeys and humans indicated that Stroop-like interference was produced by the strongly associated response tendency to pick the larger of any two numerals. This strength-of-association explanation echoes the original interpretation offered by Stroop (1935).

Not only did rhesus monkeys show the same kind of significant Stroop-like effects that were reported for human adults, but the magnitude of these interference effects was even larger for the macaques than for the undergraduates. That is, both humans and monkeys showed interference

in their relative-numerosness judgments from the irrelevant symbol-meaning stimulus dimension, but the nonhuman primates were more susceptible than the humans to influence from this strongly associated but irrelevant cue. This quantitative difference in effect size is similar to the difference that has been reported between typically developing children and children diagnosed with attention deficits (e.g., Kaufmann and Nuerk 2006) and suggests group differences in the executive-attention competencies that permit participants to override prepotent stimulus-control in favor of cognitive control by intentions, motivations, goals, or instructions. To test whether this difference between monkeys and humans in the efficiency of executive attention reflects species difference in stable cognitive competencies or only transient variations in motivation or effort, a follow-up study was conducted.

To examine the effects of cognitive control on Stroop interference, Washburn (2016) tested three rhesus monkeys on the numerical Stroop task described above. Following the procedure Kane and Engle (2003) had used to contrast the attention-control skills of humans with high versus low working-memory capacity, blocks of Stroop trials were administered between two possible trial-type probabilities. Blocks would either contain more congruent trials than incongruent trials ( $C > I$  condition: 60% congruent, 20% incongruent, 20% baseline) or no congruent trials ( $I > C$  condition: 0% congruent, 80% incongruent, 20% baseline). Kane and Engle (2003) reported greater Stroop interference effects in the  $C > I$  probability condition when compared to the  $I > C$  condition, as the former places greater demands on participants' attention-control skills (i.e., almost every trial serves to remind participants to ignore the irrelevant cue in the  $I > C$  conditions, but in the  $C > I$  condition, the irrelevant stimulus dimension actually supports fast and accurate performance on most trials, except those infrequent incongruent probe tests). As in the previous report, Washburn (2016) found significant Stroop-like effects for humans and for macaques, with larger Stroop interference for the monkeys, particularly in the  $C > I$  condition. Next, both groups were retested under the  $C > I$  condition but with a

manipulation of reward contingencies so as to determine whether Stroop interference could be attenuated when participants were incentivized to respond quickly and accurately on the incongruent trials. With increased incentives, undergraduate students were able to reduce the amount of Stroop-like interference; although response times continued to be significantly longer in the incongruent than the baseline condition, the effect size was reduced when human participants tried harder to ignore the meaning of the Arabic numerals and to respond only on the basis of stimulus set-size. The rhesus monkeys also responded faster overall under high-motivation conditions; however, this overall increase in response speed did not change the magnitude of the Stroop-like effect. When incentivized to respond quickly and accurately, the monkeys improved on baseline, congruent, and incongruent trials, but the difference between the incongruent and baseline conditions was statistically the same in the high- versus low-motivation conditions. Washburn (2016) concluded that the species difference repeatedly observed in the magnitude of Stroop-like interference was not an artifact of differences in motivation or interest between humans and rhesus monkeys but rather reflected meaningful differences in the capacity for executive control over attention (see also Washburn and Tagliatela 2012).

Bramlett-Parker and Washburn (2016) investigated whether rhesus monkeys could be trained to improve their executive-attention skills and thus to reduce the magnitude of interference from prepotent but irrelevant cues on performance. They trained rhesus monkeys on a battery of Stroop-like tasks, including the numerical Stroop task described above, a variation of the Simon (spatial conflict) paradigm (e.g., Simon and Berbaum 1990), a global/local conflict task employing hierarchically organized stimuli (for examples of this task, see Cavoto and Cook 2001, Hopkins and Washburn 2002), and a nonhuman-primate version of the ANT (Fan et al. 2002). The monkeys were alternated between attention-training blocks with the numerical Stroop and other tasks and generalization tests with the ANT to determine whether any

improvements in executive (or cognitive) control of attention would generalize. Although the monkeys were able to learn the tasks and did show Stroop-like interference as predicted, no evidence of generalized training improvements was evident in the results.

## Neural Underpinnings of the Stroop Effect

Michelet and collaborators (2007, 2009, 2015) have used a Stroop-like task for use with rhesus monkeys. These animals were trained to associate the shape of three stimuli (an outline-drawing of a banana, apple, or pear) with three response colors (yellow, red, green, respectively). When a stimulus was presented on the screen, the monkey would touch a box of the associated color from the choices at the bottom of the computer screen. Once the monkeys were trained, they were presented trials in which the fruit stimuli were colored with congruent (e.g., a yellow banana) or incongruent (e.g., a yellow apple) cue combinations. Longer response times and more errors were observed in the difficult incongruent, as compared to the baseline or easy congruent conditions.

In each of these studies, Michelet and collaborators (2007, 2009, 2015) obtained electrophysiological activity from single-neuron recordings of the monkeys. The authors reported changes in activity of cells in the dorsal anterior cingulate cortex during incongruent trials, as well as activity in the rostral cingulate motor area in response to the warning stimulus following a trial in which an incorrect response had been produced. These findings were interpreted as indicating the role of the anterior cingulate cortex in the executive control of attention by rhesus monkeys, as has been repeatedly found for human participants performing the Stroop and related tasks (e.g., Pardo et al. 1990, Posner and Raichle 1994, Posner et al. 2007). This finding is significant, because other research had failed to find evidence of the anterior cingulate cortex for executive-control performance by nonhuman primates, suggesting a critical species difference in the neural mechanisms of conflict resolution (e.g., Cole

et al. 2009, Mansouri et al. 2009). For example, Mansouri et al. (2009) used single-cell recording and lesion methods to study monkeys' cue-competition responses on a variation of the Wisconsin Card Sorting Test using incongruent flanking stimuli and found the dorsolateral prefrontal cortex but not the anterior cingulate cortex to be critical. Whereas the debate about the neural mechanisms of cognitive control for human and nonhuman animals is by no means settled, it does seem likely, as Micholet and colleagues (2016) claimed that using comparable Stroop-like tasks across investigations and species will serve to reduce the methodological differences that may result in inconsistent results and clouded generalizations.

## Conclusion

The Stroop task and its variations are more interesting than ever, because the Stroop(-like) effect is such a clear example of a failure of cognitive control. Humans and other animals can exert executive control over attention and response decisions, but the effectiveness of this control is incomplete in the face of conflicting demands from stimulus cues and the response tendencies that are associated with them. The capacity to resist interference from irrelevant but prepotent stimulus cues, as reflected in the magnitude of Stroop-like interference, appears to vary reliably across species, across development, across diagnostic categories, and as a function of particular neural systems. Given this, it seems likely that continued study of Stroop-like effects in nonhuman animals will remain important, not only for demonstrating the continuity that exists across species in the control mechanisms of behavior but also for identifying interventions that may improve the effortful and future-oriented control of attention (Washburn 2016).

## Stuck-in-Time Hypothesis

William A. Roberts

Western University, London, ON, Canada

## Synonyms

[Episodic memory](#); [Future planning](#); [Mental time travel](#)

Science fiction writers and film makers have frequently depicted stories in which people are able to use a time machine to travel to the past and future. Although no such machine exists for physical time travel, most humans time travel mentally. That is, we mentally replay episodes from our past (episodic or autobiographical memory) and anticipate or make plans for events to occur in the future. What would our lives be like, however, if we could not mentally time travel?

Tulving (1989) reported the case of a man identified as K. C., who had suffered brain damage to the left frontal-parietal and right parietal-occipital lobes of his cortex. The consequence of this injury was that K. C. no longer retained the ability to remember episodic memories of personal past experiences and could not conceive of future events. Although K. C. retained his ability to use language and general knowledge about the world (reference memory), he could no longer mentally time travel. We could say that cognitively he was “stuck in time.”

W. Roberts (2002) raised the question of whether animals might be stuck in time. That is, do animals have a sense of time as a continuum that extends backward and forward from the present moment? Do they have memories for specific past experiences and can they plan for future

activities? Considerable field and laboratory research indicates that animals remember places where food, mates, and predators are located. These are *what* and *where* reference memories based on repeated experiences. Of more interest for the stuck-in-time hypothesis is the question of whether an animal remembers specific instances of past encounters with food, mates, or predators. Of particular interest, does an animal remember not only what was encountered and where it was encountered, but also *when* it was encountered. Tulving argued that episodic memory required memory of what, where, and when a past event occurred and concluded that "Remembering past events is a universally familiar experience. It is also a uniquely human one" (Tulving 1983, p. 1).

In his 2002 review of the literature on animals' sensitivity to time, W. Roberts pointed out that there is strong evidence for animals' use of time in certain ways. Thus, animals can learn associations between time of day and where food will be found (Biebach et al. 1989). They can also keep track of intervals of time lasting from seconds to several minutes. In Pavlov's (1927) classic experiments, dogs given food every 30 min came to salivate only a few minutes before each scheduled food delivery. On a fixed-interval schedule of reinforcement, a rat or pigeon is reinforced for pressing a bar or pecking a key only after a certain amount of time has elapsed since a light or tone signal was initiated. The animal learns to withhold responding during the interval until just a few seconds before a response will earn a reinforcer. The use of the *peak procedure* pinpoints the moment in time that an animal expects reinforcer delivery and shows that it closely approximates the fixed interval (Roberts 1981). However, these demonstrations of timing by animals have been explained by neural mechanisms that do not require a concept of extended time. Thus, an internal circadian clock could explain sensitivity to time of day. A number of theories account for interval timing, most prominently the idea that a neural accumulator was used to track short time intervals (Church et al. 1994).

Beyond these demonstrations of temporal appears in animals, W. Roberts' (2002) review of

the relevant literature found little evidence of a sense of extended time, episodic memory, or future planning in animals, and he concluded that the evidence largely suggested that animals were stuck in time. Since that review, considerable new evidence has come out suggesting that animals may have a form of episodic memory. As early as 1998, Clayton and Dickinson reported evidence for what-where-when memory in scrub jays. This classic experiment rested on the fact that scrub jays in nature cache or hide food in different locations and later use their memory to retrieve their caches. In Clayton and Dickinson's lab, jays were allowed to cache highly favored wax worms in one tray and less preferred peanuts in another tray. When given the opportunity to retrieve these items 4 h later, the hungry jays not surprisingly preferred the tray where worms had been cached. On other occasions, however, jays' memory was not tested until 5 days had gone by. The jays now showed a complete reversal of preference and went to the tray containing peanuts. Of critical importance, worms in the real world would have decayed over 5 days but peanuts would still be edible. The jays' behavior suggested they understood this effect of time and chose appropriately. Clayton and Dickinson argued that jays could only have reversed their preference from worms to peanuts by remembering when the worms were cached (4 h or 5 days ago) and knowing that worms decay over that long a period.

This effect of retention interval on food preference has now been demonstrated in several other species of birds, including black-capped chickadees, magpies, and even pigeons. In variations on this procedure, similar results were found with mammals, including rats and apes. Thus, a number of species of animals showed what-where-when memory and fulfilled Tulving's original criteria for episodic memory. However, Tulving (1989) added an additional property of human episodic memory, *autonoetic consciousness* or the feeling of retrieving a personal episode. Because animals could not be quizzed about their autonoetic consciousness, Clayton and Dickinson (1998) suggested that scrub jays (and later other species) had at least fulfilled the

what-where-when criteria and should be said to have *episodic-like memory*.

Having established that episodic-like memory appears in animals, we can ask about the other direction of mental time travel. Is there any evidence that animals plan for the future? Although W. Roberts (2002) found little evidence for future planning by animals, new evidence has begun to erode that position. A common type of experiment that tests for future planning is one in which an animal can choose between two or more behaviors, with one of these behaviors being to its advantage only at some future time. For example, McKenzie et al. (2004) gave squirrel monkeys a choice between 10 and 20 peanuts. Not surprisingly, monkeys chose the tray with 20 peanuts. A pilfering manipulation was then introduced in which the experimenter returned 15 min later and took away all the remaining peanuts if 20 were chosen but not if 10 were chosen. Monkeys rapidly changed their initial choice to 10 peanuts. In another experiment, monkeys showed a preference for four peanuts over two peanuts. During a test phase, when the monkey occasionally chose the two-peanut tray the experimenter returned 15 min later and replenished the tray with eight more peanuts. Monkeys rapidly developed a preference for the two-peanut tray over the four-peanut tray.

According to a hypothesis advanced by Bischof-Kohler (1985), animals should show future planning only for rewards they currently need. Unlike humans that purchase food for meals days in advance, animals would only plan for a currently desired reward. In a test of this hypothesis, Naqshbandi and Roberts (2006) initially found that squirrel monkeys chose four dates when given a choice between four dates and one date. Monkeys had constant access to water and thus were not thirsty when they made their choice. During a block of test trials, a monkey's water bottle was removed just before it made its choice. If the monkey chose one date, the water bottle was returned in 1 h. If it chose four dates, however, the water bottle was not returned for 4 h. Monkeys' preference changed from four dates to complete preference for one date. The important point here

is that monkeys apparently anticipated a future need for water not experienced at the time they made their choice between one and four dates. Contrary to the Bischof-Kohler hypothesis, this finding suggests that an animal can anticipate a need not currently experienced.

Another example of animals planning for a future need not currently experienced comes from a well-known experiment reported by Raby et al. (2007). Western scrub jays were shown to plan in the evening for the breakfast to be consumed the next morning. Birds were trained and tested in an apparatus that contained a central compartment and two compartments on each side. For daily breakfast, birds were fed pine seeds in one side compartment on some days, but, on other days, they were put in the alternative side compartment with no seeds. In a test given the evening before breakfast, birds were fully satiated on pine seeds. Although not hungry for pine seeds, the birds could cache pine seeds made available to them in the central compartment. The important observation made was that jays cached seeds in the compartment that was always empty at breakfast. Through this behavior, they guaranteed that pine seeds would be available at breakfast the next morning, regardless of which side compartment they were placed in.

Yet another exciting area of research is planning with tools in nonhuman primates. Mulcahy and Call (2006) showed bonobos and orangutans one of two problems that required different tools in order to obtain a food reward. After seeing the problem, an ape could select one tool from several tools, only one of which would yield the reward. Further, the ape was removed from the problem area and had to wait an hour or more before it could return. Apes correctly selected the needed tool far beyond chance expectancy, and did so in the case of two animals at delays than extended overnight for 14 h. In another variation of this type of experiment Osvath and Osvath (2008) gave two chimpanzees and an orangutan a choice among four objects. After being taken from the testing room for 1 h, a subject was allowed to return where it found a favored reward, a container of fruit soup. Among the objects initially

offered the ape was a hose that it could use to suck the fruit soup from its container. The apes chose the hose far beyond chance probability. A particularly convincing final experiment was one in which the apes were confronted with four new objects. Although none of these objects was a hose, one of them could be used to extract fruit soup from its container. Apes chose the useful tool on almost all of the test trials.

A final rather amusing example of future planning comes from an observation made of a chimpanzee housed on an island in a Swedish zoo (Osvath 2009). Caretakers observed that the chimp would collect rocks and pieces of concrete and store them near the public viewing area. When visitors then appeared to see the chimpanzee, it attempted to pelt these onlookers with rock missiles. Stones were not used in contexts other than throwing at spectators, and caching stone tools was not seen during the off-season when the zoo was closed. It appeared that the chimp was storing ammunition for a specific future purpose.

The stuck-in-time hypothesis provides a nice example of progress in comparative cognitive science. The hypothesis was initially advanced as a summary of the evidence available about mental time travel in animals around the year 2000. Most of the evidence suggested animals might be stuck in time or have no episodic memory or ability to plan for the future. Spurred by lack of evidence to the contrary, comparative psychologists began to look for possible evidence of mental time travel in animals. We now have convincing findings of both what-where-when or episodic-like memory at delays that extended in several species of non-human animals, as well as evidence of future planning in food-caching birds and nonhuman primates. A major question for future research will be to what extent these mental time travel abilities in animals are like those in humans. How far back in time do animals have episodic-like memories and how far into the future can they plan for future events? To what extent do animals have a sense of time that is marked by a progression of events extending into the past and by a potential series of events extending into the future? Exciting future studies may provide us with insight into these questions.

## Suboptimal Behaviors in Gambling-Like Tasks

Thomas R. Zentall  
University of Kentucky, Lexington, KY, USA

### Definition

Suboptimal behavior involves the preference for an alternative associated with less reinforcement than the unchosen alternative.

### Introduction

Animals are continuously taking risks. An animal might risk going to the watering hole but it risks the possibility of being attacked by a predator. An animal might risk leaving the current depleting patch but it risks not finding a better one. Animals

are assumed to have evolved risk-taking strategies that are optimal for the species and their environment (e.g., the distribution of food). Sometimes, however, animals make choices that are suboptimal even after considerable experience with the probability and amount of reinforcer.

A *suboptimal choice* is one for which there is a better alternative, such as one that gets the animal more food, better survival, or increased reproductive success. Thus, if pecking one response key gets the pigeon two pellets of food and pecking a different key gets the pigeon three pellets of food, it would be suboptimal if the pigeon had a preference for the key that get the pigeon two pellets.

When animals make suboptimal choices, those choices inform us about the relatively stable mechanisms that govern their behavior. One variable that has been shown to result in suboptimal reinforcement is the delay to reinforcement. *Delay discounting* is the reduction in value of a reinforcer when it is delayed. For example, a pigeon may prefer receiving five pellets after 0.5 s over 20 pellets after a delay of 5 s. That is, by choosing the smaller amount sooner, pigeons get fewer pellets per unit time. The explanation for this suboptimal choice is that organisms (including pigeons, rats, monkeys, and humans) have evolved to prefer sooner reinforcers because, in nature, later reinforcers may no longer be there.

Although research that will be described deals primarily with pigeons, similar effects have been found in several other species (e.g., rats, starlings, monkeys, and humans).

### The Gambling-Like Task

A different kind of suboptimal choice occurs when the delay to reinforcement is held constant, but the signaled *probability of reinforcement* differs. Thus, pigeons tended to overvalue a larger amount of food despite its lower probability of occurrence. For example, a pigeon might be indifferent between a 1/3 probability of getting 20 pellets of food over a guaranteed ten pellets. Such a finding suggests that the larger magnitude of reinforcement can suboptimally overcome its lower probability.

**Suboptimal Behaviors in Gambling-Like Tasks, Fig. 1** Design of the Stagner and Zentall (2010) suboptimal choice experiment

A related phenomenon has been found when animals are given a choice between (1) an alternative that 20% of the time is followed by a signal for reinforcement (but 80% of the time is followed by a signal for the absence of reinforcement), and (2) an alternative that is always followed by a signal for 50% reinforcement (see Fig. 1; Stagner and Zentall 2010). Thus, the pigeon has a choice between 20% reinforcement and 50% reinforcement, the second providing 2.5 times as much food. Under these conditions, although pigeons have extensive experience with both alternatives, they show a strong preference for the 20% reinforcement alternative. A similar effect has been found in rats (Chow et al. 2017), Starlings (Vasconcelos et al. 2005), monkeys (Smith et al. 2017), and humans (Molet et al. 2012). With this procedure the attraction may be the immediacy of learning what the outcome will be.

When *magnitude of reinforcement* is varied, rather than probability of reinforcement, pigeons show a strong preference for getting a 20% chance of receiving a signal for ten pellets (but an 80% chance of receiving a signal for zero pellets) over getting a 100% chance of receiving a signal for three pellets (Zentall and Stagner 2011). Thus, the immediacy of learning what they will be getting after choice is not the primary mechanism responsible for the preference.

The magnitude of reinforcement manipulation bears a strong resemblance to human *unskilled gambling behavior* (e.g., lottery tickets and slot machines) in which only the laws of chance are at play. People will bet on the low probability of winning a “jackpot” while generally aware of the fact that losing is what will happen in the long run. In the case of pigeons in the Zentall and Stagner (2011) experiment, the loss is a three-pellet *opportunity cost*. That is, the guaranteed three pellet alternative is analogous to not gambling. Interestingly, for problem gamblers, losing does not appear to cause them to refrain from gambling. In fact, losing may actually encourage gamblers to gamble more, under the mistaken belief in the *gambler’s fallacy* (the belief that a string of losses must be more likely to be followed by a win). Problem gamblers are also known to be rather *impulsive*. Interestingly, when pigeons were tested for their impulsivity, those pigeons that were scored as more impulsive (as measured by the degree to which they discounted delays) were also the fastest to choose suboptimally.

### The Mechanisms Involved in the Suboptimal Choice

Findings by Zentall and Stagner (2011) suggest that the pigeons were not basing their choice on

the probability of reinforcement associated with that choice, but rather, they appeared to be using the value of the signal for reinforcement that follows that choice – the value of the conditioned reinforcer. Thus, rather than choosing between 20% and 50% reinforcement, the pigeons were choosing between 100% and 50% reinforcement. And, in the case of the magnitude of reinforcement manipulation, rather than choosing between an average of two pellets (a 20% chance of obtaining ten pellets) and three pellets, they were actually choosing between the signal for ten pellets and the signal for three pellets. Surprisingly, the signal for the absence of reinforcement appears to play little role in the pigeons' choice. In more learning theoretic terms, the signal for the absence of reinforcement does not appear to acquire inhibition.

Although the value of the conditioned reinforcer rather than the probability of reinforcement associated with the initial choice appears to determine pigeons' choice (Smith and Zentall 2016) there appears to be a second mechanism responsible for suboptimal choice. Several investigators have used variant on the procedure used by Stagner and Zentall (2010) in which pigeons are given a choice between (1) an alternative that 50% of the time was followed by a signal for reinforcement and 50% of the time was followed by a signal for the absence of reinforcement, and (2) an alternative that was followed by a signal for 100% reinforcement. Surprisingly, they have found that many pigeons still choose suboptimally. Furthermore, Case and Zentall (2018) found that continued training with this procedure actually resulted in a significant preference for the alternative that resulted in 50% reinforcement. This result, together with those of earlier studies, suggests that there must be a second mechanism responsible for the suboptimal choice. Case and Zentall proposed that the second mechanism appears to be *positive contrast* between what was expected at the time of choice and what occurred when the conditioned reinforcer appeared.

To test the role of positive contrast more directly, Zentall et al. (2019) reasoned that if one decreased the contrast between the expected

probability of reinforcement and the probability of reinforcement upon presentation of the signal for reinforcement it should reduce the contrast and thus reduce the preference for the suboptimal alternative. Intuitively, one might expect that increasing the probability of reinforcement associated with the suboptimal alternative would increase the preference for that alternative. However, when the probability of reinforcement associated with the suboptimal alternative was increased from 50% to 75%, in keeping with positive contrast theory, it decreased the preference for the suboptimal alternative. The decrease in suboptimal choice occurred because it reduced the contrast between the expected probability of reinforcement, 75%, and the probability of reinforcement upon presentation of the signal for reinforcement, 100%.

This result may explain why problem gamblers continue to gamble. If they expect to lose, because they so often do, when they actually win, the positive contrast is so great that it encourages further gambling.

## The Demographics of Suboptimal Choice

There are important similarities between suboptimal choice by pigeons and human unskilled gambling behavior. Pigeons appear to be unaffected by signals that predict the absence of reinforcement and problem gamblers appear to be unaffected by losing. The probability of reinforcement for choice of the suboptimal alternative appears to have little effect on the animal's choice of that alternative (Vasconcelos et al. 2005). Similarly, people appear to pay little attention to the probability of winning the lottery. Similar to pigeons that prefer the suboptimal, rarely occurring, ten-pellet reward, billboards advertise the magnitude of reward for guessing the winning lottery number, but they rarely indicate the probability of winning. Furthermore, independent of changing probabilities, when the value of winning the lottery increases substantially, people line up to buy tickets.

One might argue that the various procedures used with pigeons are somewhat different from

human gambling contexts. Rather than attempt to design a pigeon task more similar to human gambling, Molet et al. (2012) tested humans on a variation of the pigeon suboptimal choice task. They found that self-reported gamblers chose the suboptimal (low-probability, high-payoff) alternative significantly more than control subjects. Thus, the suboptimal choice task used with pigeons appears to be a good analog of unskilled human gambling behavior.

The demographics of human unskilled gambling behavior indicates that there is a negative correlation between the amount of disposable income an individual has and the likelihood that they will engage in unskilled gambling. To determine if pigeons show a similar phenomenon, Laude et al. (2012) varied the level of food restriction in pigeons. They found that pigeons that were less food deprived chose the suboptimal alternative significantly less than pigeons that were normally food deprived. Paradoxically, by choosing the suboptimal alternative less often, the pigeons that were presumably less hungry were actually getting more food.

Problem gamblers are known to be relatively impulsive and there is evidence that reduced impulsivity can reduce the effectiveness of conditioned reinforcers for problem gamblers. Furthermore, rats exposed to environmental enrichment have been found to show a decrease in impulsivity as measured by a decrease in delay discounting. Pattison et al. (2013) hypothesized that pigeons exposed to *environmental enrichment* might show less of a preference for suboptimal choice. When they gave pigeons experience in large cage with four other pigeons for 4 h a day, they found that those pigeons preferred the suboptimal alternative significantly less than control pigeons that had no environmental enrichment. Thus, enriched housing, even for a relatively short 4-h a day, appears to retard the development of suboptimal choice. This finding has implications for the treatment of problem gambling behavior by humans. It implies that exposing human gamblers to an environment that is socially and physically enriched also may reduce the attraction of gambling.

## Conclusions

The mechanisms responsible for suboptimal choice by pigeons are likely to have broad generality and although the behavior appears to be paradoxical, it can be explained by two relatively simple learning mechanisms. The value of conditioned reinforcers (independent of their probability) and positive contrast (between the expectation of reinforcement and the positive reinforcer that results). Understanding these mechanisms may not only explain the suboptimal behavior but may also aid in the treatment of humans whose suboptimal gambling behavior is detrimental to their health and to their social relations.

## Subsong

Ednei B. dos Santos  
GIGA – Neurosciences, University of Liège,  
Liège, Belgium

### Definition

Subsongs are vocalizations produced by juvenile songbirds at the initial stage of vocal motor development. These vocalizations are soft (sung at low amplitude), show high variability of vocal elements, and lack the structural and temporal organization of adult songs.

### Introduction

Songbirds share with humans the sensorimotor ability to imitate sounds, vocal learning. This is a very distinctive trait that evolved only in three groups of birds (songbirds, hummingbirds, and parrots) and in a few other mammals (Jarvis 2004). The process of vocal learning in juvenile songbirds resembles in many ways the stages which human infants go through to acquire a native language. As in humans, they learn songs by imitating adult conspecifics, a “tutor.” Vocal learning initiates during early development and involves a sequence of sensory and sensorimotor

developmental phases. Subsongs are produced by juvenile songbirds at the first stage of vocal motor development. They have been compared to babbling in human babies for hardly resembling fully developed songs produced by adult songbirds (Doupe and Kuhl 1999). Subsongs are followed by additional sensorimotor stages in which songs gradually start to resemble adult songs.

## The Auditory Template Hypothesis

Pioneering research programs conducted by William Thorpe, Peter Marler, Mark Konishi, and others led to the proposal of a highly influential birdsong development model known as the auditory template hypothesis (reviewed in Soha 2017). According to this hypothesis, songbirds are born with an innate mechanism, or template, that guides them through a two-stage sensorimotor song development process.

### Sensory Acquisition Phase

A critical period for song learning starts just after young songbirds leave their nests. During this period, they need to be exposed to adult songs, in order to successfully develop songs with their species-typical characteristics. At this stage, songbirds are especially sensitive to adult conspecific songs. They are able to promptly memorize songs and use them as models to guide the subsequent sensorimotor phase of song development.

### Sensorimotor Phase

The sensorimotor phase consists in the gradual development of a motor program in which the singing output of young songbirds is guided by the stored memory of adult songs memorized during the sensory acquisition phase (Marler 1991). The timing between the end of the sensory phase and the beginning of the sensorimotor phase may vary widely across different species. In seasonally breeding species, such as white-crowned sparrows (*Zonotrichia leucophrys*), juvenile birds start to produce subsongs several months after they have been exposed to an adult and memorized its songs (Hultsch and Todt 2004). However, in nonseasonal breeding species, the

interval between the sensory acquisition and sensorimotor phases is shorter and can even overlap. For example, in zebra finches (*Taeniopygia guttata*) juveniles start to produce subsongs while still memorizing adult songs. Their sensory acquisition phase lasts from 25 to 65 days post-hatch (dph). But after reaching 35 dph they already start producing subsongs (Zann 1997).

The sensorimotor phase is typically subdivided into three stages: subsong, plastic song, and crystallized song. Subsongs are produced at the earliest stages of vocal motor development. These are soft and highly variable vocalizations. Plastic songs, as its name suggests, are still very variable, but they already contain several vocal elements and temporal organization patterns found in adult songs. At the end of the sensorimotor phase, after a gradual decrease in variability, songs are said to be crystallized, i.e., they become fully developed adult songs with stable structural and temporal patterns.

## Structure and Function of Subsongs

Subsongs barely resemble adult songs. For this reason, they have been compared to the babblings of human babies and other mammals (Doupe and Kuhl 1999). Subsongs are noticeably softer than fully developed adult songs and show great variability of its constituent vocal elements (notes and syllables). They also show no consistent structural and temporal patterns. For example, adult zebra finch songs are composed of vocal elements that are produced in a fixed sequence called “phrase.” However, subsongs produced by juveniles of this species lack stereotypy in the sequential organization of phrases and also in the duration and shape of vocal elements (Aronov et al. 2008).

## Vocal Motor Practice and Exploration

It has been suggested (Hultsch and Todt 2004) that subsongs function as a stage of vocal practice and exploration in which juvenile songbirds can learn how to coordinate the sounds produced via syrinx (the songbird’s two-voiced vocal apparatus) and to develop fine sensorimotor control. According to this idea, the production of highly

variable vocalizations at the initial stage of the sensorimotor development allows juveniles to learn how to establish causal relationships between motor commands and sound production. A similar function has been proposed for human babbling (Doupe and Kuhl 1999).

## Beyond Vocal Imitation

Tchernichovski and Marcus (2014) called attention to the fact that reaching exact copies of tutors’ vocalizations is not the usual developmental goal of vocal learning in songbirds and humans. Instead, the process of vocal learning leaves some range for the production of variation. Imitation is not the only ability developed during the process of vocal learning. The development of the combinatorial ability to rearrange vocal elements is another important goal of the vocal learning process. Vocal learning is a much more complex process than a one-to-one interaction between a tutor and a tutee. It is also influenced by the dynamics of social interactions. Juvenile zebra finches, for example, can imitate songs from multiple tutors and mix them to form new unique repertoires (Jones et al. 1996).

## Neurobiological Basis of Subsongs

Songbirds are the main animal models used to investigate the neurobiological basis of vocal learning. They have a “song-system,” a set of interconnected brain nuclei specifically dedicated to song learning and production. Two main pathways controlling song production and learning have been identified. The vocal motor pathway involved in sound production includes the forebrain nuclei NIf (nucleus interfascialis), HVC (acronym used as a proper name, formerly known as High Vocal Centre), and RA (robust nucleus of the arcopallium). RA projects directly to a motor nucleus that controls respiration and muscular activity in the syrinx. The anterior forebrain pathway also connects HVC to RA through an indirect route that includes the area X of the lobus parolfactorius, DLM (medial nucleus of the dorsolateral thalamus) and LMAN (lateral magnocellular nucleus). The anterior forebrain is

involved in the regulation of vocal learning. Lesions to LMAN in juvenile songbirds at the stage of subsongs or plastic songs can disrupt learning and production, whereas lesions in adults do not seem to affect songs (Doupe et al. 2000).

Surprisingly, Aronov et al. (2008) have shown that the production of subsongs is not mediated by the same set of brain nuclei involved in the production of songs in adults, the vocal motor pathway. They have demonstrated that juvenile zebra finches do not require HVC, a key nucleus involved in adult song production, to produce subsongs but require LMAN (which is not involved in song production in adults). Aronov and collaborators concluded that subsongs are not generated by an immature vocal motor pathway. They suggested the existence of two distinct motor pathways that produce vocalizations at different stages of development.

## Conclusion

Songbirds develop vocal learning through a sensory-motor process that is strikingly similar to the way human infants acquire a native language. As in humans, this process requires social interactions, sensory feedback, and vocal practice. The first vocalizations produced by juvenile songbirds are called subsong. They are highly variable vocalizations that hardly resemble adult songs. Subsongs may function as a form of vocal exploration in which juvenile songbirds learn how to coordinate the sounds produced by their vocal apparatus. Some research results indicate that subsongs are not mediated by the same brain nuclei involved in the production of songs in adults.

## Substance Withdrawal Syndrome

- Withdrawal

## Subtraction

Rosa Rugani  
University of Padua, Padua, Italy

### Definition

Performing subtractions requires the capability to estimate the resulting difference between a first number, or quantity, minus a second one.

### Introduction

In the field of animal numerical cognition, the capability to master subtraction is considered a complex numerical capacity, because it requires a manipulation of at least two numerical representations to produce a new representation (Vallortigara et al. 2010). The capability to subtract, together with the capability to perform additions, is the only arithmetic ability which has been proved in animals.

Arithmetic has been mainly investigated in animals for what concerns physical sets of objects. Animals' arithmetic abilities differ from humans' abstract arithmetic calculations. The latter are based on a complex system of symbols which refers to numbers and operation that can be performed on numbers, for example,  $45 - 27 = 18$ . Hence, these can be defined symbolic-numerical abilities. Nonsymbolic numbers refer to the information that can be extrapolated from physical events, hence in absence of symbols.

### The Unfortunate Beginning of the Study of Arithmetic Ability in Animals

Arithmetic operations, more than other numerical abilities (such as, e.g. numerical discrimination, which is the capability to discriminate two sets of objects on the basis of their numerosities; and ordinal abilities, which is the capability to identify an element in a series of identical elements on the basis of its numerical position in that series),

suffer of a certain skepticism after the unfortunate beginning of the Clever Hans story (Pfungst 1907). Hans was a horse that, in the first decade of the twentieth century, was trained by his owner, to execute a multiplicity of symbolic arithmetic calculations, which ranged from subtractions, to summations, to divisions, to long square roots. When Hans was presented with an arithmetical operation, he responded by tapping his hoof on the ground the correct number of times. The initial enthusiasm on clever Hans' mathematical skills vanished when it was unveiled that Hans responded correctly only when its owner knows the correct answer, and Hans could see him. Hans was surprisingly skillful in perceiving subtle behavioral signals made by its owner, while it was reaching the correct count with its hoof tapping. As a consequence the great delusion generated by Clever Hans' story pervaded animal numerical research and lasted for decades. Numerical competences were considered as strictly linked with the possibility of using language and symbols; therefore, mathematical reasoning was considered a prerogative of adult and educated humans. Nevertheless, increasing evidence has demonstrated that nonverbal creatures (human infants and nonhuman animals) master arithmetic calculation (Dehaene 2011; Brannon and Roitman 2003).

### Subtractions in Human Infants

The seminal study on arithmetic abilities in nonverbal creatures goes back in 1992, when Caren Wynn showed that 5-month-old infants successfully answered to simple summations and subtractions. The idea was that if infants keep track of the numbers of toys they have seen being placed behind a screen they should look longer at the screen that, when lowered, revealed an outcome that violated their expectations (violation of expectation paradigm, VoEP). For example, in the  $2 - 1 = 1$  or 2 task, infants were showed two toys that were placed behind a screen; then one was removed. In some instances the outcome was expected ( $2 - 1 = 1$ ), and in other cases the revealed number was unexpected ( $2 - 1 = 2$ ). Infants looked longer at outcomes where

expectation was violated (Wynn 1992), suggesting that they are able to solve simple arithmetical problems.

### Subtractions in Adult Animals

To test arithmetic calculation in a population of semi-free-ranging monkeys (*Macaca mulatta*), it has been designed a paradigm which exploited the optimal foraging theory (Krebs 1974). This theory assumes that animals, when can choose between two food alternatives, spontaneously prefer the one that maximizes energetic gain (i.e., larger amount of food). Subjects viewed two different numbers of identical food items that were positioned behind two identical screen. For example, three items were hidden behind a screen and two behind the other one. Some items were then visibly removed from behind the screens. For example, one item was removed from both screens, 3–1 versus 2–1. Monkeys approached the screen that hid the larger number of food items (Sulkowski and Hauser 2001). This demonstrates that primates can solve simple subtractions without having received specific numerical training.

Interestingly enough, arithmetic abilities have been proved also in bird species.

Using a VoEP paradigm, wild New Zealand robins (*Petroica australis*) have proved to solve simple subtractions, such as 2–1 or 3–1. Within view of the bird, a certain number of food items were subtracted from an initial amount of items, placed in a container. For example, from an initial set of three items, one was removed (3–1). Robins were then allowed to approach the container. When the number of found items violated the arithmetic rules, robins searched longer than when the number was arithmetically congruent, proving their proto-arithmetical competences (Garland and Low 2014).

### Subtractions in Young Animals

To understand how early animals can start to use numerical information, arithmetic task has been investigated in young domestic chicks (*Gallus*

*gallus*), which is a species that can master different kinds of numerical tests, ranging from numerical discrimination of artificial social companions (Rugani et al. 2010) to ordinal abilities (Rugani et al. 2007).

Newly hatched domestic chicks were reared with five identical objects that through exposure were treated by the chicks as social companions. On day 3, chicks underwent free choice tests. At first they were shown different sets of objects to disappear, one by one, behind one of two opaque identical screens (first event). Subsequently some of the objects were visibly transferred, one by one, from a screen to the other (second event). For example, four objects were first hidden behind a screen and one behind the other. Then one or two objects were transferred from the screen hiding four to the screen hiding one object. In both cases chicks approached the screen hiding the larger number of “social companions” (Rugani et al. 2009). Results suggest impressive proto-arithmetic capacities in very young and relatively inexperienced chicks.

### Conclusions

Studies on animal numerical cognition suggest that numerical information is so relevant that a variety of animal species master simple arithmetic abilities. Interestingly enough the paradigms used, such as the VoEP paradigm and the spontaneous choice based on the optimal foraging theory, allowed to test the capability to perform summation and subtractions in untrained animals. This suggests that to solve simple numerical operations, animals do not need a long numerical training. Moreover, data on newborn chicks show that numerical information is so relevant that almost naive animals naturally extrapolate and use it soon after birth.

## Synonyms

Nipple attachment; Suction

## Antonyms

Weaning

## Definition

The terms nursing and suckling are both related to lactation (milk acquisition). Yet, nursing is from the female's perspective – the act of providing milk – while suckling is from the infant's viewpoint – the act of obtaining milk from a nipple.

## Introduction and Terminology

Suckling and nursing are terms sometimes used interchangeably, but each has very distinctive meanings. The act of suckling refers to the offspring perspective, the acquisition of milk from a nipple. As for nursing, it includes physiology and behavior of the lactating female in order to transfer milk to an offspring (Hall et al. 1988). The authors emphasize that many behavioral interactions are required for both to be successful. In essence, the young searches, recognizes, and attaches to a nipple, a stimulatory requirement for the milk transfer from the lactating female. Although behavioral interactions are indeed necessary for suckling/nursing to be successful, the morphological apparatus is quite interesting.

Therefore, we will first present morphological aspects that enable suckling/nursing behavior, followed by the physiological cascades and, finally, the behavioral characteristics that make this entire mechanism feasible.

## Morphological Aspects for Nursing

Extant mammals are divided into monotremes, marsupials, and placentals. Monotremes, the egg-laying mammalian group, produce a nutritive substance similar to milk, but adults do not present nipples that would allow infants to perform an appropriate suckling. The young receives this substance through skin-feeding, in which the “milk” exudes and is thick enough to cling in the female’s hair, so it can be licked directly (McLoughlin 1980). Conversely, marsupials and placentals have specialized structures called nipples, teats, or udder, where their young are able to attach to and obtain milk. After attachment, suckling occurs and, eventually, milk is released (see Physiology section). Together, both this specialized structure and this particular behavior avoid milk waste and ensure a more effective transport of nutrients to the young (McLoughlin 1980; Blass 1990).

## Morphological Aspects for Suckling

Suckling is unique to mammals and intimately connected with cranial features: palates, facial muscles, cheeks, lips, and tongue compose this complex apparatus, required for the development and evolution of suckling in mammalian neonates. Concerning skull morphology, mammals present a hard palate, a structure found in pre-mammalian species and responsible for the complete separation of breathing and swallowing, allowing both to occur at the same time (Hiimeae and Crompton 1985; Maier et al. 1996).

Still considering skull traits, mammals present a unique feature regarding dental replacement, called diphyodont dentition, that can be defined as two different dentitions throughout a lifetime. A consistent pattern is the young being born

without teeth, with subsequent eruption of milk teeth and further replacement by permanent teeth. Being born toothless possibly enhances suckling performance and, in turn, a liquid nourishing exempts the immediately need of teeth and masticatory movements. This delay in tooth eruption and replacement grants an extra time for skull growth, so there is enough space in the oral cavity for all the permanent teeth (Pond 1977). Although this perspective seems constantly reinforced in some studies, it still requires a broader phylogenetic comparison.

Besides osteology, suckling involves a specialized musculature working synchronously. One muscle seals completely the roof of the mouth, separating breathing and swallowing, another group of muscles creates a low pressure and bring in the liquid, and a third muscle group helps swallowing (Crompton et al. 2018). Marsupials and placentals present all these muscles and can perform suckling. Monotremes, however, do not possess some of these muscles, and the long hard ossified beak hampers their ability to suckle. Yet, this statement is still controversial since a few authors consider that suckle activity is possible (Koyama et al. 2013; Li et al. 2016).

Likewise, mouth parts are essential for suckling motion. For instance, it is necessary a regular and rigid tongue movements to prevent air passage so that inside-out pressure between female nipple and offspring mouth is maximized. Moreover, lips seal completely the mouth and the nipple together (Elad et al. 2014). Finally, saliva is an underestimated, but crucial component as it acts as a mechanical sealant to the infant lips at the female’s nipple. Rats with no submaxillary-sublingual saliva died of starvation, due to the inability to suckling properly (Epstein et al. 1970).

## Physiology of Suckling/Nursing

Nursing is deeply associated with lactation, which has been defined as the physiological state of a female mammal resulting in milk production. Besides nourishment (water, proteins and fat), milk is also responsible for the postnatal transfer of immune protection to the young since

premamalian species (Blackburn et al. 1989). Antibodies can be transferred to the offspring either during pregnancy (exchange with their mother blood) or ingestion after birth. Different antibodies require different transfer paths as some are not capable of crossing the placenta, for instance. Therefore, milk ingestion is an important way of acquiring immune protection, particularly rich in the first milk, also known as colostrum (Boulinier and Staszewski 2008).

Lactation includes milk synthesis by specialized cells found in mammary glands. During adulthood, mammary glands go through four stages: mammogenesis (cell proliferation), lactogenesis (milk production and let down), galactopoiesis (maintenance of milk production and let down), and involution (milk production ceases and the tissue shrinks). After milk production, it passes through mammary ducts (from the alveolar epithelium to the alveolar lumen) all the way to the nipples in marsupials and placentals, but directly to the exterior in monotremes (Hall et al. 1988). Although the description of lactation cycles is beyond our scope, these phases are highly dependent on many hormones, from sex steroids to protein hormones (Svennersten-Sjaunja and Olsson 2005).

Despite that many hormones are essential for lactation to occur, two are intimately associated with the process of nursing/suckling: prolactin and oxytocin. The two are secreted at basal levels, in both sexes, but they increase at extraordinary speed and up to 10 times higher during suckling. While prolactin is important for milk production, maintaining the constant milk metabolism, oxytocin is involved in milk ejection control (Svennersten-Sjaunja and Olsson 2005). Neither hormone requires a preceding pregnancy as the nipple stimulus is enough to induce milk production. Therefore, allonursing (nursing for another female's offspring) is possible even in non-pregnant females (see section below).

It is interesting that suckling triggers what is called milk letdown reflex. Why would a mammal need such reflex? Because suckling alone does not cause milk flow even with the negative pressure caused by the infant at the nipple. The cascade is as follows: suckling stimulates oxytocin release

that, in turn, stimulates contraction of milk ducts and creates a positive pressure at the female's body. The act of suckling is able to open the valves, so that milk ejection is now possible (Goodman 2009).

Hormonal release and milk production can be stimulated either by increasing suckling duration or by increasing the number of teats suckled. Hence, during the postnatal period, nursing is more recurrent and lasts longer, so that hormonal discharge is higher. A similar pattern can be observed in larger litters as multiple teats are suckled simultaneously.

Oxytocin has another important influence: pair bonding, particularly between the nursing female and the suckling offspring (Uvnäs-Moberg 1998). Higher levels have been detected after affectionate contact between adults and infants by inhibiting our defensive behavior and reducing our natural avoidance response. Because its release is stimulated by suckling, as the infant grows older, nursing sessions are reduced both in frequency and duration, lowering the production of both hormones (Ziegler et al. 2004). Hence, this hormone has important specific behavioral effects.

## Behavior of Suckling/Nursing

As stated above, nursing and suckling require behavioral interactions in order to be executable. From the pups' perspective, besides search and attachment, additional behaviors may follow, such as kneading, treadling, and/or butting movements to help milk transfer. Kneading and treadling is when a young uses its paws to induce milk ejection from a teat, pressing against the maternal ventrum (Smotherman and Robinson 1994; Barrows 2011). Butting could be equivalent to the kneading/treadling behavior as it is more common in hoofed-mammals. Instead, the young induces milk ejection with its own head by pressing against the female's teats. This sequence of events helps maintain nipple contact and stimulate milk letdown, ejection, and withdrawal.

Many authors employ an additional term, named as "sucking." However, in the work of

Hall et al. (1988), they define sucking as being only the negative intraoral pressure on the nipple caused by repeated mouth movements, necessary for milk ejection. They emphasize that sucking and suckling are not synonyms because sucking may not result in milk ingestion, occurring at nonlactational periods. Thus, sucking is a part of suckling. Sometimes, nipple contact may provide infant comfort and does not include suckling necessarily. We can find a good example in humans when kids suckle the index finger for soothing, but they do not obtain any milk.

Lastly, it is important to emphasize that nursing/suckling does not include a mother and her infant(s) necessarily as many species show allomaternal lactation. Thus, we use “female” and “offspring/young,” because they may not be related. For instance, carnivores and primates have many examples of allomaternal lactation (allonursing, allocare) in which a female lactates for an offspring other than her own, without even the need of having her own offspring or being pregnant.

## Conclusion

Suckling is one defining characteristic of mammals. It is attributed to the act of suckle from infants aiming milk ingestion, and there are many morphological aspects essential for it to occur. A hard palate, cheeks, tongue, and lips work together for this complex system to be in motion. As for nursing, many mammals present specialized structures, called nipples, teats or udder. Since monotremes do not present these structures, some authors argue that they do not perform suckling. Regardless, nursing refers to the physiology and behavior of the lactating female in order to transfer milk to an offspring. Lactation is essential for infant survival through feeding and immune protection. Milk production involves many hormones, but mostly prolactin and oxytocin, which are associated with the act of nursing/suckling. However, hormonal secretion does not require that the female is pregnant since the nipple stimulus is enough to induce milk production. Therefore, allonursing is possible in

nonpregnant females and that is why the terms “female” and “offspring/young” instead of “mother” and “offspring/young” are more appropriate. Suckling and nursing help social bonding between female and infant, providing instant recognition and physiological signals to continue the milk production.

## Sue Savage-Rumbaugh

Jennifer M. Johnson<sup>2</sup> and David A. Washburn<sup>1,2</sup>

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

Emily Sue Savage-Rumbaugh (August 16, 1949–) is a comparative psychologist and primatologist known for her studies of language and development in bonobos (*Pan paniscus*) and chimpanzees (*Pan troglodytes*). Her research with apes – most

notably chimpanzees Sherman, Austin, and Panzee, and bonobos Kanzi and Panbanisha – have resulted in more than 100 publications, including the books *Ape Language: From Conditioned Response to Symbol* (Savage-Rumbaugh 1986) and *Kanzi: The Ape on the Brink of the Human Mind* (Savage-Rumbaugh and Lewin 1994, coauthored with Roger Lewin). She has received numerous honors, including honorary degrees from the University of Chicago and Missouri State University. In 2011, *Time Magazine* named Dr. Savage-Rumbaugh one of the 100 most influential people in the world.

## Personal and Professional History

Sue was born in Springfield, Missouri to Euell Rubert, who was in real estate, and Joyce Rubert, a homemaker. As a child, she was interested in all school subjects, but quickly found her passion in psychology at Colorado College. She later transferred to Southwest Missouri State University (now Missouri State University) where she graduated with honors in 1970 with a B.A. in psychology. After graduation, Sue Savage planned to go to Harvard for graduate study with B.F. Skinner. However, fate interceded: the fellowship she was expecting fell through, but more influentially, a visit with a friend at the University of Oklahoma (OU) changed the direction of her interests. During her visit to OU, Sue sat in on a lecture by ape-language researcher Dr. Roger Fouts, who had brought a chimpanzee named Booe to class to demonstrate the sign-language research being done at the Institute for Primate Studies (IPS; aka “The Farm”) which had been founded at OU by psychologist Dr. William Lemmon. It was a life-changing experience for the young psychology scholar, as she later recalled: “At that time I was studying child development and had a 2-year-old son who was beginning to acquire language. I was amazed to see a chimpanzee sit in front of a class of 100 students and sign...” (Hillix and Rumbaugh 2013, p. 155). She moved to Norman, OK, and began doctoral training under the direction of Professor Lemmon, earning her M.S. in 1972 and the Ph.D. in 1975. Because

the colony of chimpanzees at IPS had been reared in various ways, including wild-caught, peer-reared, mother-reared, and in human homes, Sue was able to study the effects rearing environments had on chimpanzee development. She found that the rearing conditions, combined with sign-language training, created a perfect cauldron for research on chimpanzee behavior. Her dissertation was an ethnography of intentional gestures and postures in group-living chimpanzees, looking at the use of these behaviors for communicative purposes.

After receiving her degree, Dr. Savage accepted a position in Atlanta, GA, conducting postdoctoral research at the Yerkes Regional Primate Research Center. In Atlanta, her experience with chimpanzees and with language-acquisition research would be of great value, as she joined the Language Analog (LANA) Project – an ambitious, NIH-funded multidisciplinary research enterprise directed by Dr. Duane Rumbaugh, professor and chair of psychology at Georgia State University. LANA Project scientists were studying whether a chimpanzee named Lana could learn to communicate using a specially designed computer-based keyboard and a “language” of visuographic symbols called lexigrams. Dr. Savage brought new perspective to the 3-year-old project, helping to document aspects of Lana’s impressive performance, but also providing insightful criticisms of some of the LANA Project’s limitations.

The professional move with her son to Atlanta contributed to the end of Sue’s marriage with William Savage, Jr., now an emeritus professor of history at OU. In 1976, Sue and Duane Rumbaugh wed. They were married for more than two decades, and remain friends and collaborators to the present day.

The juxtaposition of experiences in Oklahoma and Georgia served to convince Dr. Savage-Rumbaugh of the importance of the social functions and context of language. These social aspects were largely absent from the work with Lana, which was focused on communications by the chimpanzee with the computer and with human researchers. A new group of four chimpanzees (Austin, Erika, Kenton, and Sherman)

was assigned by the Yerkes Center to the language-training project in 1975, although ultimately the demands of raising young chimpanzees in a language-rich environment would require the research team to focus their efforts on Austin and Sherman only. The communicative medium for this new research remained lexigram word-symbols and the computerized keyboard, but the goals of the so-called Animal Model Project were shifted dramatically by Savage-Rumbaugh. Whereas Lana was taught to produce sequences of lexigrams in stock-sentences so as to achieve desired outcomes (e.g., make requests, ask and answer questions) from the computer or human caregiver, the foci of research with Austin and Sherman were on communication between the chimpanzees, and on determining what the symbols might mean to the apes (i.e., on comprehension rather than production). Savage-Rumbaugh endeavored to establish, with and between the apes, the same kinds of social connections that human infants experience when they learn language. Project scientists taught the apes to share food, to exchange tools, and to use the keyboard to tackle problems that could not be solved without the use of symbols. In one such test, Sherman used the computer keyboard to request foods that were accessible by Austin; Austin, in response, would retrieve the food items that Sherman requested, give Sherman half, and consume the remainder. No human experimenter was present in the room as the apes performed these tests! The training and tests with Austin and Sherman were reported in numerous published articles and extensively detailed in a book and accompanying video documentary (Savage-Rumbaugh 1986). The book also described research led by Dr. MaryAnn Ronski (Georgia State University) to derive principles from the work with Lana, Sherman, and Austin, and to apply those principles in language interventions for nonspeaking children and young adults with intellectual disabilities.

Although Austin and Sherman showed impressive evidence of conceptual understanding and communicative use of the lexigram symbols, they consistently failed Dr. Savage-Rumbaugh’s controlled tests of spoken-English comprehension

in the absence of contextual cues. However, a very different story would emerge when Savage-Rumbaugh shifted the focus of her research to bonobos—a shift that, in many ways, came almost by accident! In 1981, Dr. Savage-Rumbaugh was attempting to teach a bonobo named Matata to use lexigrams. The teaching methods that had been so successful with Austin and Sherman seemed ineffective with Matata, whose attention was largely devoted to young Kanzi, the ever-present infant Matata had adopted when he was 6-months old. Matata's utter lack of progress in learning lexigrams made it easy to spare her when it was time for her to return to the Yerkes Center for breeding, whereupon the 30-month-old Kanzi immediately and without prompting began to use the lexigram keyboard, and doing so to make requests and to announce actions with surprising accuracy (Hillix and Rumbaugh 2013). Although Matata had failed to benefit from the training, her adopted son Kanzi had clearly learned a great deal from observation.

This event catalyzed another radical shift in the ape-language research that Dr. Savage-Rumbaugh directed. She concluded that that language is an active cognitive process that is not solely behaviorally shaped. Indeed, attempts systematically to train apes to use language can also limit the depth of what they learn. Rather, in the correct language-rich environment, focused on comprehension and functional significance of symbols, apes can come to learn language the way that human children do, and the way Kanzi apparently did. Dr. Savage-Rumbaugh's subsequent research with bonobos Kanzi, Mulika, Panbanisha, common chimpanzee Panzee, and many other apes followed this new method, modeled much more closely after the rearing of human children.

Apes raised in this language-rich social culture also showed that they could comprehend not just lexigram-based communications, but also the spoken English used by Dr. Savage-Rumbaugh and other speakers. Unlike Austin and Sherman, Kanzi (and other apes raised like him) passed carefully controlled experimental assessments of spoken-word comprehension. In one extensive study, Kanzi was tested, under conditions that controlled for cuing and experience, for his ability

to comprehend novel sentences of spoken English. The bonobo performed comparably to a typically developing 2½-year-old human child on these tests, showing sensitivity both to word meaning and to the way that sentence meaning is determined by word order. The monograph report of these findings (Savage-Rumbaugh et al. 1993) was named by the University of Minnesota Center for Cognitive Science as one of the 100 most influential works in cognitive science in the twentieth century.

Professor Savage-Rumbaugh attempted to untangle the potential effects of species versus training variables in producing the performance differences that were observed between chimpanzees Austin and Sherman on the one hand, and bonobos like Kanzi on the other. Beginning in 1985, she led a longitudinal research project in which she and her research team coreared an infant chimpanzee (Panzee) and an infant bonobo (Panbanisha), and studied the physical, behavioral, and cognitive similarities and differences between these language-experienced apes – as well as the ways that the two apes were unlike language-trained animals that had been studied earlier (e.g., Brakke and Savage-Rumbaugh 1995, 1996).

From 1981 to 2005, Dr. Savage-Rumbaugh studied these and related topics with the apes at Georgia State University's (GSU) Language Research Center (LRC). In 1987, she was appointed Associate Professor of Biology at GSU and earned tenure in 1990. She retired as a GSU Professor of Biology and Psychology in 2005 and moved with the bonobos to the Iowa Primate Learning Sanctuary and Great Ape Trust in Des Moines, IA. She is currently President of Bonobo Hope, a nonprofit organization.

## Significant Contributions

Dr. E. Sue Savage-Rumbaugh has dedicated over four decades to great apes, serving as primary caregiver, teacher, researcher, and advocate for more than a dozen chimpanzees and bonobos. Without discounting the able assistance she received from collaborators, students, and staff

(including Sally Boysen, Karen Brakke, Heidi Lyn, Rose Sevcik, Jared Taglialatela, and many others), a few scientists in history have embraced the intense, constant, longitudinal commitment of raising apes in this way – much less doing so multiple times. Her methods and conclusions have been criticized, but she has been tenacious in the debate. Her publications included many controlled tests of ape cognition that appeared in refereed journals, and she succeeded in attracting many years of extramural funding for her research, primarily from the National Institute of Child Health and Human Development. Her work has also generated considerable media attention. Documentary recordings of her work, particularly with Austin, Sherman, and Kanzi, provide important archival records and instructional resources.

In 1981, Dr. Savage-Rumbaugh assisted Dr. Duane Rumbaugh in establishing the Language Research Center (LRC) at Georgia State University. The LRC provided a home to the remarkable resident chimpanzees and bonobos, a laboratory for Dr. Savage-Rumbaugh and countless other scientists to study these unique primates, and a strong commitment to promoting the health and psychological wellbeing of all of the Center's animals. The LRC was, and continues to be, an important resource where students can be trained and scientists of various disciplines can study primate behavior and cognition.

Across her career, Dr. Savage-Rumbaugh's research and writings have increasingly emphasized the importance of enculturation. The animals learn about ape culture from other apes. They learn some rules and routines of human culture from researchers, teachers, and caregivers. These experiences don't make the chimpanzees and bonobos any less apt representatives of apes, but the cultural experiences and expectations of a laboratory-raised animal are different, even unique. The effects of this enculturation manifests in a wide range of behaviors, including those like tool-making, numerical cognition, vocal production, social cognition, and language comprehension that have been studied by Dr. E. Sue Savage-Rumbaugh (e.g., Hopkins and Savage-Rumbaugh 1991; Sevcik and Savage-Rumbaugh 1994; Tomasello et al. 1993).

## Superior Parietal Lobule (SPL)

Claudio Galletti and Michela Gamberini  
Department of Pharmacy and Biotechnology,  
University of Bologna, Bologna, Italy

As shown in Fig. 1a–b, the parietal lobe of both human and nonhuman primates can be distinguished in anterior and posterior subdivisions. The posterior parietal cortex, in turn, is divided into superior (SPL) and inferior (IPL) parietal lobules, separated by the intraparietal sulcus. According to Brodmann (1909), the superior parietal lobule, the target of the present chapter, hosts two cytoarchitectonic fields, area 5 anteriorly and area 7 posteriorly. In the human brain, area 5 is a quite restricted area while area 7 occupies most of the SPL (see close-up in Fig. 1a). In the macaque brain, instead, area 5 occupies most of the SPL and area 7 only a restricted region of cortex in the caudalmost part of SPL (see close-up in Fig. 1b). Several studies in the last century claimed that this latter cortical region is not area 7, as originally indicated by Brodmann, but a variation of area 5. In either cases, it remains that the cytoarchitecture in SPL is not uniform, and the different architectural patterns of anterior and posterior

parts of SPL suggest that they host different functional properties and subserve different functional roles.

The following is a summary of the functional properties, anatomical connections, and possible functional roles of SPL. The description refers to the macaque SPL, which has been intensively studied in the last decades. The human SPL has been much less studied to date and has not been taken into account here.

## Functional Properties of the Macaque SPL

In 1982, Pandya and Seltzer (1982) proposed a subdivision of the macaque SPL which is still used today in most of the scientific works related to the posterior parietal cortex (Fig. 1c): the anterior part of SPL, dominated by Brodmann's area 5, was named area PE while the posterior part of SPL (area 7, or a variation of area 5) was named area PEc, where “c” stands for “caudal.”

Area PE is a somatosensory area, like the Brodmann's areas 3, 1, 2 that occupy the post-central cortex just anterior to PE (Fig. 1). Area PE, however, shows some functional differences with respect to the other somatosensory areas. While areas 3, 1, 2, in particular areas 3a and 1, are dominated by tactile representation and host a detailed map of the entire body, PE is dominated by proprioceptive representation (see Fig. 2b, columns on the left) and hosts a rough topographical map of the body, with an overrepresentation of the arm, particularly of the hand (Fig. 2a). PE neurons are generally sensitive to multi-joint stimulations and to the posture of the limbs. Often, the neuronal responses of single PE cells are evoked by somatic stimulations of different parts of the body, mainly of the contralateral side, but sometimes of the ipsi or even of both ipsi and contralateral sides (Fig. 2b, right). It has been demonstrated that PE neurons are also involved in the preparation and control of limb movements, and become active during skilled actions (Fig. 2c). This means that PE is not simply a somatosensory area, as originally thought, but a somatomotor area that hosts motor signals together with a

somatosensory map of the body. It has been suggested that it contributes to the somatomotor guidance of motor behavior. Area PEc, differently from PE, is an area that hosts a quite large visual field representation together with an incomplete somatosensory map of the body. The visual neurons of PEc are quite large and are often sensitive to the optical flow. The body map is focused on the proximal parts of

the limbs and does not show any evident sign of topographical organization (Fig. 3a). The somatic PEc neurons respond mostly to single-joint rotations but also to tactile stimulations of the trunk and limbs. The incidence of joint versus tactile sensitivity, as well as of contralateral versus ipsi and bilateral sensitivity, is almost the same as that shown by area PE (Fig. 3a, bottom). Several single PEc neurons show bimodal somatovisual

Area PEc

**Superior Parietal Lobule (SPL), Fig. 3** Functional properties of area PEc. (a) *Top*: Distribution of functional properties within area PEc. Notice the absence of any somatotopy. Abbreviations: Cs central sulcus, IPs intraparietal sulcus, Ls lunate sulcus, POs parieto-occipital sulcus, STs superior temporal sulcus, PE, PEc areas PE, PEc, Center; *left*: Density map of PEc visual receptive field (RF) distribution. Gray scale indicates the relative density of RFs covering that specific part of the visual field. *Center, right*: Body locations of PEC somatosensory RFs: joint RFs are represented as dots and tactile RFs as colored regions of the body. The size of each dot and the intensity of colored regions are proportional to the number of modulated cells. All somatosensory RFs have been reported on the left side of the body. *Bottom*: Incidence of joint and tactile cells (*left*) and of contralateral, ipsilateral, and bilateral modulations (*right*) in area PEc (Modified from

Breveglieri et al. 2008). (b) Depth and direction tuning of the activity of a PEC neuron. Spike histograms and rasters of cell activity are shown for nine target positions presented to the animal at eye level, but with different depth and direction (see inset on the top left). Notice that the cell was strongly activated when the animal reached the far contralateral target and, like PE neurons, discharged during both movement preparation and execution. HB home button (Modified from Hadjidimitrakakis et al. 2015). (c) Perievents time histograms of the activity of a PEC neuron recorded while the animal reached a target located in eight different spatial positions on a two-dimensional plane starting from the center. The color-coded map of cell activity shown on the bottom center represents the location and extent of the visual RF of the neuron as determined during a Visual Fixation task (Modified from Ferraina et al. 2001)

known to be involved in the skeleton motor control of limb movements. Interestingly, PEC is more strongly connected with the motor and premotor cortical regions representing the lower

limbs than with those representing the upper limbs.

In summary, all the cortical sensory afferents to PE bring only somatic information while those to

**Superior Parietal Lobule (SPL), Fig. 4** Summary of main cortico-cortical connections of areas PE and PEc. Cortical connections of area PE (**a**) and PEc (**b**) are shown in *orange* and *green*, respectively. Only projections representing more than 3% of the total cortical connections of that area are reported here. The thickness of connecting lines is proportional to the strength of connections, averaged across all cases with injections in the same area (Data

obtained from Bakola et al. 2010, 2013). Abbreviations: *ps* principal sulcus, *as* arcuate sulcus, *cal* calcarine fissure, *cin* cingulate sulcus, *cs* central sulcus, *lf* lateral fissure, *ls* lunate sulcus, *pos* parieto-occipital sulcus, *sts* superior temporal sulcus, *ips* intraparietal sulcus. F1, F2, F3, PEc, PE, PEci, PEip, 3, 2, 23, 24, 31, PGop, PG, Ri, V6Ad, MIP: areas F1, F2, F3, PEc, PE, PEci, PEip, 3, 2, 23, 24, 31, PGop, PG, Ri, V6Ad, MIP

PEc bring both somatic and visual information. Both areas also receive motor signals related to limb movements.

**Conclusions**

The cortical afferents of areas PE and PEc corroborate the functional characteristics of these areas, being PE essentially a high-order somatosensory area and PEc a bimodal somatovisual area, albeit with predominant somatosensory inputs. Both areas overrepresent the limbs, more the upper than the lower one. However, while PE shows an overrepresentation of the distal part of the upper limb, similarly to areas 3, 1, 2 (Fig. 2), PEc overrepresents the proximal part of both upper and lower limbs (Fig. 3). The functional properties as well as cortical afferents of areas PE and PEc strongly suggest the involvement of both areas in the control of limb movements. This is in line with the functional roles proposed for PE and PEc, the former being suggested to be involved in the preparation/execution of limb movements, in

particular the movements of the upper limbs, and the latter in the control of limb movements and of interaction of the four limbs with the visual environment. Since area PEc is sensitive to the optical flow, receives visual information mostly from the lower visual field, and is more strongly connected with cortical motor/premotor regions that represent the lower limbs, it has been suggested that it is involved in the visual guidance of locomotion.

## Superior Temporal Sulcus

Laura Cuaya and Raúl Hernández-Pérez  
Universidad Nacional Autónoma de México,  
Queretaro, Mexico

The superior temporal sulcus (STS) is located longitudinal to the lateral surface in the temporal lobe and is immediately parallel to the lateral

fissure. The STS ranges from the angular gyrus to approximately one centimeter before the temporal pole. The STS separates the superior temporal gyrus and middle temporal gyrus.

## Functions

The STS is a multisensory high-order association cortex that processes social information.

*Face perception* (Allison et al. 2000; Haxby et al. 2000). The STS is important in the changeable aspects of a face. Beyond identity, it is crucial to the communication of dynamic aspects from faces like lip movement, eye gaze to infer attentional state, and the emotional expression (Allison et al. 2000; Hagan et al. 2009; Peelen et al. 2010; Robins et al. 2009; Said et al. 2010). The model of the distributed human neural system for face perception includes the STS in the core system involved in the visual analysis of a face, whereas the inferior occipital gyrus processes the early perception and the fusiform gyrus, the invariant perception of faces, the STS process the changeable features of faces (Andrews and Ewbank 2004; Kanwisher and Yovel 2006). The STS also has reciprocal connections with inferior occipital and fusiform gyrus, and with nodes of the extended system: intraparietal sulcus, auditory cortex and amygdala, and insula and limbic system.

*Multisensory integration* (Beauchamp 2005). In macaques and humans, the STS plays an important role in multisensory integration. In both species, the STS has a patchy organization for multisensory integration, with patches that prefer meaningful stimuli of one sensory modality (e.g., auditory or visual), and other multisensory patches, that responds to both kind of stimuli (e.g., auditory and visual) with an enhanced response to multisensory integration. This organization suggests that the different sensory modalities arrive in specific patches depending on the sense, since each sense has a specific neural code in the patches that could facilitate the transformation into a common code. Furthermore, in these multisensory patches occur the integration of the different modalities into multisensory representations.

## Mentalizing in Autism Spectrum Disorders

The autism spectrum disorders (ASD) imply impairments in social perception (e.g., eye-gaze, voice, and visual perception) that are highly correlated with anatomical and functional abnormalities in the STS.

For example, the ability to attribute mental states to others is affected in ASD. This process was explored in a classical study (Castelli et al. 2002). To remove the human component in the mentalizing process, the researchers designed three animations of two triangles with different interactions between them: random movement, goal-directed movement, and movement that implied intentions, to relevant mental processing. The cerebral activity while the participants viewed the animations was compared between normal and ASD adults. Regarding mental processing of the animation, the results showed a weaker activation in a network that includes bilateral STS, prefrontal cortex, and temporal pole in the ASD group. However, the activity in an extrastriate region (V3) was the same in both groups. The main finding of this study was that despite the same increased activity in V3 in both groups, the functional connectivity between V3 and the STS was reduced in the ASD group. The results suggest a lack of modulation of anterior regions to the STS, and that this promoted an interruption in communication between high order (STS) and low order (V3) perceptual regions. It was more difficult for ASD group to recognize the social meaning of the triangle's movements. It is important to emphasize that the impairment in the ASD group is due to a problem in the functional connectivity in the STS, which shows the importance of the cerebral networks in the social perception.

## Human Specific Asymmetry in the STS

Humans show several behavioral and neuroanatomical asymmetries, and some of these asymmetries also are present in nonhuman primates. However, an astonishing study comparing

magnetic resonance anatomical images from 177 humans and 73 chimpanzees suggests that the asymmetry in the STS is exclusive of humans (Leroy et al. 2015). The human sample included subpopulations: infants, children, adults, women, men, right-handers, left-handers, and an atypical population (i.e., autistic spectrum disorder, situs inversus, Turner syndrome, and corpus callosum agenesis). They found that in 95% of all human's subpopulations, a 45-mm-long segment ventral to Heschl's gyrus is deeper in the right hemisphere than in the left hemisphere. It seems that this anatomical asymmetry is specific to humans, because this anatomical asymmetry in the STS was not significant in the chimpanzee sample. These results are supported by an independent meta-analysis that included chimpanzees and macaques (*macaca mulatta* and *m. fascicularis*), which did not find differences between the left and right STS in different anatomical measures (e.g., depth, total surface areas, specific and total length) (Hopkins et al. 2015). The fact that the asymmetry in the STS is widely shared among humans through the lifespan and even in atypical populations, but is absent in macaques and chimpanzees, could suggest that the social cognition supported by the STS has a different development and manifestation in humans.

## Supernormal Stimulus

### ► Innate Releasing Mechanism

## Supernumerary Nipple

Hare Krishna

Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Jodhpur, Rajasthan, India

## Synonyms

Accessory nipple; Ectopic nipple; Extra nipple; Polythelia

## Definition

Supernumerary nipple is the presence of one or more extra nipples with or without an areola or accessory breast tissue on the body.

## Introduction

A supernumerary nipple is a minor developmental abnormality of mammary tissue. It is most commonly located over the ventral surface of the thorax and abdomen along the embryonic milk lines. The embryonic milk lines extend from the axilla to the groin. It is most commonly located below the normal position of the nipple. It is one of the most common types of mammary tissue malformation. Most of the cases of supernumerary nipple appear to be sporadic and asymptomatic. In some families, several generations of people are effected with polythelia, so its inheritance may be familial. But some authors found that it is also genetically inherited as autosomal dominant with incomplete penetrance and X-linked dominant (Halleland et al. 2017).

It appears as a solitary or multiple brown-colored protuberance along the milk lines. In majority of the cases, the size of supernumerary nipples are smaller (2–3 mm in diameter) than the normal nipple (Mohammed 2019). Sometimes, it may look like a pigmented nevus or a fibroma. In such conditions microscopic examination can be done to confirm the clinical diagnosis. On doing so, lesions show features of hyperpigmentation and presence of pilosebaceous follicles and smooth muscles like nipple and areola (Mehregan 1981).

## Epidemiology

Depending on various epidemiological factors like sex, ethnicity, and geographical area, the incidence of polythelia ranges between 0.22% and 5.6% in the general population (Singal et al. 2016). The incidence of supernumerary nipple is 0.22% in a white European neonates where as in African American neonates, it is around 1.63% (Sun et al. 2018). It is more common in males in comparison with females. Black neonates are more affected than white neonates. There is a higher prevalence for the left side in comparison with right (Singal et al. 2016). Supernumerary nipple is present bilaterally in approximately 50% of people with polythelia.

## Classification

The well-accepted classification of supernumerary nipple was given by Kajava in 1915:

1. Complete supernumerary nipple consists of nipple, areola, and glandular tissue.
2. Supernumerary nipple consists of nipple and glandular tissue (no areola).
3. Supernumerary nipple consists of areola and glandular tissue (no nipple).
4. Supernumerary nipple consists of anomalous glandular tissue only.
5. Supernumerary nipple consists of nipple and areola and pseudomamma.
6. Supernumerary nipple consists of nipple only (most common).

7. Supernumerary nipple consists of areola only (polythelia areolaris).
8. Supernumerary nipple consists of only patch of hair (polythelia pilosa) (Halleland et al. 2017).

## Sites

1. Most common thorax or abdomen (65%) and axilla (20%)
2. Unusual sites:
  - (a) Face (Koltuksuz and Aydin 1997)
  - (b) Foot (Conde et al. 2006).
  - (c) Male perineum (Leung et al. 1997.
  - (d) Back and shoulder (Mohammed 2019)

## The Embryogenesis of Supernumerary Nipple

Supernumerary nipple is formed early in the development of the embryo. During fourth week normally a pair of epidermal thickenings called the mammary ridges develops along the milk lines on either side of the body. In humans, these ridges normally disappear except at the site of future breasts. Failure of regression of mammary ridges up to the third month of embryogenesis results in the formation of the supernumerary nipple.

## Association of Supernumerary Nipples with Various Systems

1. Urinary system – Supernumerary nipple is most commonly associated with kidney and urinary tract malformations, including renal adenocarcinoma, renal cysts, bilateral hydronephrosis, duplicate renal arteries, double renal pelvis and ureter, polycystic kidneys, hypoplastic kidney, microcystic kidney, and renal agenesis (Brown and Schwartz 2004).
2. Cardiovascular system – Cardiac conduction defect especially left bundle branch block, cardiac arrhythmias, hypertension, congenital heart diseases (Miranda 2012).
3. Gastrointestinal tract – Pyloric stenosis (Miranda 2012).

4. Central nervous system – Epilepsy, spina bifida occulta, tethered cord, diastematomyelia (Dogan et al. 2015).
5. Musculoskeletal system – Congenital scoliosis.
6. Supernumerary nipple may be associated with several syndromes like popliteal pterygium syndrome, Simpson-Golabi-Behmel syndrome, Becker nevus syndrome, and Char syndrome (Dogan et al. 2015). Simpson-Golabi-Behmel syndrome is a rare syndrome which is caused by an X-linked gene (Fonseca and Cantin 2014).

## Treatment

- Usually no surgery
- Surgery performed for cosmetic reasons or any complication in the breast tissue

## Conclusion

Various studies suggested that the supernumerary nipple is not only limited to cosmetic concern, but it may be associated with various systemic anomalies and syndromes. Therefore, in every newborn, there should be routine physical examination to search for accessory nipples. If any newborn has supernumerary nipple, he/she should be evaluated clinically for central nervous system, gastrointestinal system, respiratory system, skeletal system, and cardiovascular system malformations. There should be guidelines on how to manage newborn with supernumerary nipples.

## Superorganism

Adam L. Cronin  
Tokyo Metropolitan University, Tokyo, Japan

## Definition

A group of organisms which function together in a highly integrated way to accomplish tasks at the group level such that the whole can be considered collectively as an individual.

## Introduction

The term “superorganism” helps convey the idea that groups of individuals can function as, and

thus be considered as, singular entities, and as such, be subject to natural selection at the group level. Coinage of the term has been attributed to James Hutton, who in 1789 used it to describe the collective geophysiology of the Earth. Its most common contemporary use is in describing highly integrated animal societies, particularly those of social insects (Hölldobler and Wilson 2009).

## Social Insects as Superorganisms

Of all animal societies, few can match the sophistication and organizational complexity of the social insects (some bees and wasps; all ants and termites) and these organisms have frequently been championed as the epitome of the superorganism concept (Hölldobler and Wilson 2009; Seeley 1996). In social insect colonies, workers perform the manual tasks of the colony such as defense, construction, brood-care, and maintenance, while queens lay the eggs. Workers in many social insects are sterile, and as such have been compared to the somatic cells of a unitary multicellular organism. The queen(s), on the other hand, serves as the reproductive organ(s) of the superorganism. Queens and workers are mutually interdependent, as while workers are sterile, many queens cannot survive without worker assistance. Thus, while neither of these components can persist and procreate on their own, they together comprise a complete functional unit.

## Superorganisms Outside of the Social Insects

Social insects are well suited to the superorganism concept because they form highly integrated societies composed of clearly delineated individuals. The distinction between group and individual is spatially and/or temporally less distinct in other organisms which nonetheless deserve the label of superorganisms. Siphonophores, for example, are hydrozoans which form colonies of individual zooids exhibiting a marked division of labor. Zooids are asexually produced from the same embryo and are so highly integrated they were long considered to be single organisms (Dunn

2009). Slime molds, on the other hand, are usually free-living individual amoeboids but can assemble into a motile slug under starvation conditions. These slugs can further differentiate into reproductive structures exhibiting a distinct reproductive division of labor in which “spore” individuals are supported by nonreproductive stem-forming individuals.

Other purported examples of superorganisms are more equivocal: the human body has been regarded a superorganism comprising a human “host” and its bacterial community. However, while microbial communities can have an impact on our health, it may be more appropriate to consider the human body as an ecosystem populated by microorganisms, which can be affected by its constituent biota in the manner of all ecosystems.

## Characteristics of Superorganisms

*Emergence:* Superorganisms are characterized by emergent phenomena: group-level processes and/or characteristics arise through local interactions between individuals without any top-down control. In this manner, superorganisms can perform complex tasks without any individual component having knowledge of the whole, or having advanced intelligence. The concept of emergence reflects the complexity of superorganisms, in acknowledging the difficulty in extrapolating observed group-level phenomena from the interactions and behavior of individual components. For example, social insect colonies exhibit consistent behavioral characteristics at the level of the group (“personality”; Jandt et al. 2014). This group level trait is an emergent product of the personalities of its component individuals and can vary between superorganisms. Groups can also benefit from collective immunity, both in terms of prophylaxis and immune responses (Cremer et al. 2007). Honeybee colonies, for example, can eliminate bacterial infection by increasing brood-comb temperature when multiple individuals increase their body temperature to generate a “social fever.”

*Reproduction:* Reproduction in superorganisms occurs when a new superorganism is produced.

In social insects, for example, this means the establishment of a new colony, either by a new queen or a dispersing swarm containing queen (s) and workers (Cronin et al. 2013). Production of sterile workers can be considered as a maintenance operation, as this is concerned with the upkeep of the “body” of the organism rather than its propagation.

*Specialization:* Individuals comprising superorganisms typically exhibit a division of labor, and specialization on particular tasks may be associated with the evolution of distinct types of morphology (castes) such as queens and workers. Both of these factors can increase the efficiency and effectiveness of group task performance.

*Social Structure:* The social organisms which provide the best fit to the superorganism concept are “eusocial.” Eusocial organisms are characterized by reproductive division of labor, overlapping generations, and cooperative care of offspring.

## Scope of the Terminology

The superorganism concept has been challenged on various fronts, particularly associated with opposition to evolutionary group selection arguments. Furthermore, it is often derided as taking the analogy between unitary multicellular organisms and groups too far, because while the cells of unitary organisms are clones, individuals in groups in most cases are not (though they may be highly related). Application of the terminology may be best limited to circumstances in which the perspective it provides can generate useful insights, rather than merely as a badge of aggrandization.

## Conclusion

There is little doubt that superorganisms exist and that the superorganism concept can help generate new insights into the evolution and ecology of group-living organisms. It remains the subject of debate, however, as to exactly how far the remit of the term “superorganism” extends. Nonetheless, its application is likely to grow

with the increasing use of holistic approaches that emphasize the importance of the global entity, and as studies of complex systems advance our understanding of the importance of interactions in describing group level behavior.

## Superstition Experiment (Staddon and Simmelhag 1971)

Kenneth M. Steele  
Department of Psychology, Appalachian State  
University, Boone, NC, USA

## Synonyms

[Adventitious reinforcement](#); [Spurious correlation](#);  
[Superstitious behavior](#); [Superstitious reinforcement](#)

## Definition of Superstitious Behavior

Vyse (1997) described the difficulty of defining superstitious behavior because it is often a catchall for both the mysterious and mundane activities that we observe in other people. It is often a pejorative term to describe differences between the choices made by the observer and the person being observed. The term, here, refers to a specific situation. How good are nonhumans (and humans) at recognizing a causal relationship between an action and its consequence? Can they be “fooled” into persisting in a behavior even though it does not cause that consequence?

## Skinner (1948) Superstition Experiment

Skinner (1948) reported on the behavior of pigeons that were exposed to a series of presentations of food at regular intervals, irrespective of their behavior (a *fixed time* [FT] schedule; also described as a Pavlovian temporal conditioning procedure). There are many missing methodological details from the article: Missing are number of subjects, number of sessions, exact time intervals, method of identification of responses, temporal contiguity of the different responses to food, and rate changes among those responses. All of those issues are glossed over in a casual presentation in the report. Most descriptions focused on a subset of the results where a FT 15-s schedule was used, with a 5-s food presentation, and a verbal summary is reported.

However, Skinner’s interpretation of the results was vivid and influential. He described a reinforcement effect that was due to *temporal contiguity of response and reinforcer alone*: “. . . conditioning takes place presumably because of the temporal relation only, expressed in terms of the order and proximity of response and reinforcement” (Skinner 1948, p. 168). The reinforcement effect operated on an idiosyncratic range of responses occurring across subjects, including walking counterclockwise, head bobbing, head swinging, and pecking. Skinner concluded that almost any behavior was susceptible to the influence of accidental correlation of a response and a

reinforcer. The effect was strong, requiring more than 10,000 responses before *extinction* (disappearance of the response) in one pigeon. He ended the short article with an extension to human behavior in the description of a bowler wagging at an errant ball, suggesting the power of contiguity of responses and reinforcers to maintain behavior in the absence of a true causal connection. Skinner’s interpretation of the effect of spurious connections of response and consequence is termed *adventitious reinforcement* (Sidman 1960) commonly.

## Staddon and Simmelhag (1971) Reexamination of the Superstition Experiment

The historical context of the Staddon and Simmelhag (1971) experiment was the occurrence of several puzzling findings in the animal learning literature. Breland and Breland (1961) reported that food-related behavior emerged in animal training and supplanted the reinforced response, even though this new behavior delayed delivery of the reinforcer. For example, a raccoon trained to deposit a token coin for food would spend additional time in the food-related behavior of “washing” the coin instead of depositing the coin to obtain quickly the reward. Williams and Williams (1969) reported that it was very difficult to train a pigeon *not* to peck a lighted disk when it predicted food. Falk (1969) reported that other activities, such as excessive water consumption, would emerge in the post-reinforcement period in a (response-contingent) *variable interval* (VI) or *fixed interval* (FI) food reinforcement schedule when food was not available. The motivation to engage in these activities was strong enough that water could operate as a reinforcer in this period if a response was required to obtain the water. These odd results suggested that Skinner’s superstitious behaviors may be controlled by factors other than accidental temporal contiguity of response and reinforcer.

The general design of the Staddon and Simmelhag (1971) experiment is simple. Behaviors are recorded during a (response-independent)

FT interval of food presentation for the individual pigeons. Skinner would predict that whatever response occurred with greatest contiguity to food on initial trials should increase in frequency across trials. The increase should occur as food presentation became more likely. Responses are likely to vary across birds, due to the accidental nature of the original pairing.

The actual method was more complicated. Six pigeons (two with prior experimental experience) were used. The pigeons were exposed to a series of sessions without food in order to develop the set of response categories. Obtained response categories ranged from continuous (R1: head and body oriented toward magazine) to discrete (R7: pecking toward magazine wall) and somewhere in between (R9: preening, any movement in which beak contacts feathers).

Three different reinforcement schedules were used, FI 12-s, FT 12-s, and (*variable time*) VT 8-s. (The FT and VT schedules were defined as response-*independent* FI and VI schedules in the original report.) Reinforcement was 2-s access to mixed grain. Two birds were exposed to all three schedules, two birds were exposed to only the FT and VT schedules, and two birds were exposed to only the FT schedule. The acquisition and *steady-state* (last three sessions) data were analyzed.

## Results of Staddon and Simmelhag (1971)

### Acquisition Results for Bird 49

The acquisition results for (experimentally naïve) Bird 49 (Fig. 3, Staddon and Simmelhag 1971) encapsulate a major finding of the study. Behavior during the 10- to 12-s portion of the FT interval is of importance because this is the period closest in time to food delivery. Bird 49 spent more than 90% of its time with its head in the food magazine for the first seven sessions during this time period. This result was to be expected because that behavior is contiguous with obtaining food. Abruptly, this response is displaced by pecking on the magazine wall, and pecking became the primary response during this period for the next

29 sessions. Staddon and Simmelhag reported a similar transition with the other five pigeons.

The result was a direct contradiction of the Skinner (1948) contiguity account. The high-frequency response closest in time to food is not maintained. Instead it was replaced abruptly by another response that had not been occurring frequently in prior sessions. The result is reminiscent of the food-related response intrusion effects reported by Breland and Breland (1961).

### Steady-State Behavior

The birds were reported each to settle into a pattern of a small number of responses that occurred in a reliable sequence. The responses were categorized into two classes. *Terminal responses* were activities that occurred consistently before food delivery, typically starting about halfway through the interval. *Interim responses* were activities that began before the terminal response. The classification of an activity as interim or terminal was based on its temporal location during the interval. What could be a terminal response for one bird could be an interim response for another bird. Note the case of Bird 49, cited previously, where pecking began as an interim response and ended as the steady-state terminal response.

## Theoretical Analysis by Staddon and Simmelhag (1971)

The analysis began with the result that the FT food schedule generated a series of different responses (interim and terminal) that occurred in a reliable sequence for individual birds. The results were consistent with findings that show that reinforcement schedules will induce a variety of behaviors beyond the contingent or terminal response. These interim behaviors occur when reinforcement probability was low and have included polydipsia (excessive drinking), pica (eating nonfood material), and wheel-running depending on the activities that were available (Falk 1969). The activities are anomalies according to a traditional Law of Effect because the activities are not contiguous with reinforcement and are not necessary for reinforcement. They had been explained

previously as a result of adventitious reinforcement, the spurious correlation between responses and reinforcement. The question was whether to treat these cases as anomalies or to try to include them in a revised approach to the law of effect. Staddon and Simmelhag rejected the treatment of interim behaviors as odd, anomalous behaviors because they can be observed reliably under wide-ranging conditions. Therefore, they assumed that the activities must have functional significance.

Staddon and Simmelhag identified a critical procedural difference between laboratory learning experiments and the tasks faced by an animal in the wild. Laboratory learning experiments focused on one important requirement (e.g., food or water) and measured a single response related to obtaining that requirement. In the wild, animals must contend with a variety of requirements (e.g., not just one requirement but both food *and* water). Animals are faced with the issue of the best *allocation* of activities to satisfy several different requirements. Therefore, there is evolutionary selection pressure to produce a mechanism that will generate *switching* to new activities. An ideal time to switch would be when current access to a requirement is blocked in order to pursue other requirements. This was the evolutionary analysis that was applied to the results with the FT 12-s food schedule.

A pigeon is deprived of food. The deprivation activates a *state*, defined as a motivational condition in which food-related behaviors are generated and those that produce food are likely to be reinforced. The set of food-related behaviors that are generated come from personal history, species history, and situational circumstances. The Law of Effect selects among these several behaviors. The FT schedule provides food to a food-deprived pigeon on a regular temporally defined basis. Behaviors that become terminal activities are food-related behaviors that are selected as food delivery becomes more probable. They are not randomly emitted activities.

Importantly, interim behaviors are generated in a similar fashion. The time after food delivery is a period of low food probability. Low food probability is a period during which evolution-

developed mechanisms produce a *switch to other activities* so as to satisfy the other requirements. Therefore, nonfood activities develop during these time periods of low food probability. These activities are not randomly emitted either. They are state-induced and are related to other concurrent requirements for life. Other activities can be reinforced by other consequences during these periods, such as a rat pressing a lever to produce access to water even though the rat is not water deprived (Falk 1969). The variety of activities that will occur and be reinforced during this food-free period will depend also on the subject's history, species history, and the structure of the situation. Staddon and Simmelhag (1971) noted the close functional similarity among interim behaviors, adjunctive behaviors (Falk 1969), and the displacement activities, observed in European animal behavior studies (McFarland 1966; Tinbergen 1952).

### Legacy of Staddon and Simmelhag (1971)

Several important consequences followed their results. The first was that the results revealed an important flaw in the analysis of Skinner (1948). Temporal contiguity of response and reinforcer did not explain why one response became the terminal response in the situation. Responses that showed good contiguity initially could be replaced by another response with continued experience. A second important result was to argue, against a dominant operant conditioning metaphor at the time, that responses were "emitted" seemingly at random and then trapped into repetition by contiguity with a reinforcer. Instead, both terminal and interim activities were generated in a causal manner that was related to the variety of survival requirements to be met by the subject. A third consequence was that the study pointed out a conceptual issue with many American animal learning studies, and that was the sole focus on a single consequence and the rate of a single response in obtaining that consequence. The results suggested an unexplored issue was the allocation of behavior for an animal when

dealing with multiple requirements and multiple responses. Staddon continued to examine this issue (e.g., Staddon 1980).

An established interpretation (like Skinner's emphasis on temporal contiguity of response and reinforcer) is often accompanied by odd exceptions (like Breland and Breland's observation of displacement of the reinforced response). The legacy of Staddon and Simmelhag (1971) was to rearrange the order of central observations and exceptions to reconnect interesting behavioral effects with a Darwinian analysis of the origin and maintenance of behavior.

## Survival Processing

Stephanie A. Kazanas

Department of Counseling and Psychology,  
Tennessee Technological University, Cookeville,  
TN, USA

### Synonyms

Adaptive memory; Fitness relevance; Mnemonic device; Survival relevance

### Definition

A memory advantage for words, pictures, and other stimuli processed for their value in a survival scenario.

### Introduction

At the intersection between the cognitive psychology and evolutionary psychology literatures lies survival processing. In this paradigm, participants read a brief passage, encode a list of words, and perform a memory task. Researchers manipulate the nature of the brief passage, such that some participants engage in survival processing:

In this task we would like you to imagine that you are stranded in the grasslands of a foreign land, without any basic survival materials. Over the next few months, you'll need to find steady supplies of food and water and protect yourself from predators. We are going to show you a list of words, and we would like you to rate how relevant each of these words would be for you in this survival situation. (Nairne et al. 2007, p. 264)

Participants in other conditions read instructions about moving to a foreign land or simply rate words according to their pleasantness or autobiographical self-reference. Across numerous comparisons, survival processing often “wins,” in that these participants recall a greater number of words than participants in other conditions (Kazanas and Altarriba 2015; Nairne and Pandeirada 2016; Schwartz et al. 2014). These findings replicate

across within-subjects designs (Nairne et al. 2008), recognition tasks (Cho et al. 2018), and visual stimuli (Otgaar et al. 2010), as well as other languages (Kazanas et al. *in press*) and age groups (Aslan and Bäuml 2012), in addition to other manipulations and factors.

### Mechanisms and Limitations

Researchers offer a number of explanations for this important finding. For example, the ancestral nature of *the grasslands of a foreign land* and the similarly ancestral priorities of *finding steady supplies of food and water* speak to the function of memory itself: to prioritize memory for fitness-relevant information and situations (Nairne et al. 2007). In addition to – or perhaps, in support of – these functionalist explanations, researchers also suggest the role of physiological arousal when engaging in survival processing (Fiacconi et al. 2015), as well as planning (Klein et al. 2011) and self-reference (Klein 2012). Cognitive explanations have their support, as well, most notably the distinction between the types of word processing recruited for survival processing and its various control conditions. Burns and colleagues explain the effectiveness of survival processing in its recruitment of both item-specific and relational processing, relative to control conditions recruiting just one (i.e., item specific *or* relational processing; Burns et al. 2011, 2013). Most likely, the traditionally evolutionary explanations underlie these cognitive mechanisms, with both factoring into this memory advantage.

In some important exceptions, survival processing does not *always* promote better memory. For example, memory advantages do not replicate for tasks involving faces (Savine et al. 2011), implicit memory (Tse and Altarriba 2010; Wilck and Altarriba 2019), paired-associate learning (Schwartz and Brothers 2014), or online processing (Altarriba and Kazanas 2014). Generally, these exceptions have helped researchers identify “boundary conditions” for this effect, suggesting survival processing enhances memory in most, but not all, tasks and scenarios. These exceptions also point to the enhanced elaboration needed to

engage in survival processing, relative to the other word rating conditions. For example, studies show diminished memory advantages when participants consider just a single survival problem (e.g., a need for water), rather than the typical survival scenario, which asks participants to consider the need for water, food, protection from predators, and so on. These smaller effects suggest the typical survival scenario activates more elaborative encoding, which in turn provides more numerous retrieval cues during recall (Kroneisen and Erdfelder 2011). Tasks that limit participants' opportunity to engage with the to-be-remembered materials in this way are thus less likely to show an effect. Similarly, studies testing survival processing under conditions of high cognitive load (e.g., multitasking) also show reduced memory advantages over other conditions (Kroneisen et al. 2013; Nouchi 2013; Kazanas et al. 2015).

Nairne and Pandeirada (2016) propose a general survival optimization system accounting for many suggested mechanisms (e.g., ancestral priorities, arousal), in addition to the published exceptions and limitations. They describe an ultimate mechanism for this effect, with a highly flexible system of cognitive resources for detecting and responding to threats. This flexibility can account for survival processing advantages extending to scenarios describing various environments (e.g., the jungle, space; Kostic et al. 2012), predators (e.g., supernatural; Kazanas and Altarriba 2017; Soderstrom and McCabe 2011), eras (e.g., modern, ancestral; Weinstein et al. 2008), and more.

## Future Directions and Conclusions

Memory advantages following survival processing are widely replicated; with that, researchers now turn to extensions of this literature, namely the larger area of adaptive memory (of which survival processing is one example). Topics pertaining to animacy effects, cheater detection, contamination effects, mortality salience, and more are explored for their own insights into this phenomenon. Broadly,

investigating the stimuli and conditions most salient to our survival help us better understand the function of human memory.

Professor Susan Denise Healy (born on 4 December 1962, Wanganui, New Zealand) is a cognitive ecologist working at the Centre for Biological Diversity in the School of Biology at the University of St Andrews in Scotland. Her research is influenced by the common question of whether an animal's behavioral ecology correlates with its cognitive abilities and neural processes. She has integrated neuroanatomical studies with behavioral experiments of the spatial abilities of a diverse number of bird species to understand the underlying mechanisms responsible for the differences in behavior we observe in nature. So far, her research has produced over 127 original and review papers on diverse topics ranging from the neuroanatomy of food-storing birds, the cognitive abilities related to foraging behavior of wild hummingbirds, nest building, song and vocal mimicry of wild and laboratory bird species, the relationship between stress and memory, to decision-making and sex differences in spatial abilities. Although the majority of her research has used bird species as a model, she has also studied the behavior of mammalian species including humans (e.g., Jones and Healy 2016).

Sue, as most people call Professor Healy, started her career in her country of birth, New Zealand. Although she first started her studies thinking she would become a medical doctor, thanks to the good influence of teachers and fellow students, she switched majors and in 1984 Sue finished a degree in Zoology and Physiology from the University of Otago, Dunedin, New Zealand. She then travelled to the UK with the original plan of doing a little bit of work, some European backpacking and then returning to New Zealand for a PhD. Instead, Sue started a research assistantship with Professor Lord J. R. Krebs and ended up staying at the University of Oxford for 8 years. At Oxford, she did her DPhil at St Hilda's College and then she moved to the St John's College as a Junior Research Fellow. When Sue was still doing her DPhil with John Krebs as her adviser, the animal behavior group in Oxford was a hive of the most influential behavioral researchers past and present (e.g., Sara J. Shettleworth, Nicola Clayton, David Sherry and Marian and Richard Dawkins, among others).

Sue and these researchers, either as mentors or as peers who would eventually become life-long collaborators, would engage in long scientific discussions both in the lab and at the pub, a tradition that she carries out now with her own students and peers. Back in 1989, Sue published her first paper on the topic of hippocampal specialization of food-storing birds and over the years that paper has gone on to be cited more than 500 times (Krebs et al. 1989). As Sue and colleagues expected, the bird species that store food during the fall to survive the winter depended more on their spatial memory to retrieve their caches were also found to have a relative larger hippocampus (the part of the brain that process and stores spatial information) compared to species that do not store food. Adaptive specialization of spatial abilities of food-storing birds continued to be the focus of Sue's DPhil and postdoc. She focused both in species comparisons of neural anatomy and behavior and the developmental differences between different British bird species.

Still in Oxford Sue met, then postdoc, Professor Andrew T. Hurly with whom she has now published over 30 papers of original research on the cognitive abilities of wild rufous hummingbirds with focus on the spatial abilities these birds have in order to feed from hundreds of flowers a day (Healy and Hurly 2013). Sue and Andy's work with Canadian wild hummingbirds has not only been a further corroboration of how foraging ecology correlates with the cognitive abilities of animals but has also laid the foundations for ways to study cognition in wild-free living animals (Pritchard et al. 2016).

As she moved up through the academic ladder, her geographic location too, moved "up." She started in the south of the England and has now reached the Kingdom of Fife in the south of Scotland where she lives now with her partner Dr. David Shuker, a behavioral ecologist interested in insect reproductive behavior. After her time in Oxford, Sue first took a position as a Lecturer at the University of Newcastle, where she began her long-term collaboration with an old Oxford friend, Professor Candy Rowe. During her appointment at the University of Newcastle, she continued to investigate the correlates and

intricacies between hippocampal structure and the spatial abilities of food-storing birds (as tested in laboratory experiments). At the same time, she started to spend her summers in the Canadian Rockies at the University of Lethbridge's research station collaborating with Andy Hurly to establish the study of the spatial abilities of rufous hummingbirds in the wild (*Selasphorus rufus*; Healy and Hurly 1998).

In 1999, Sue moved to the University of Edinburgh where she stayed there for 10 years. There, Sue focused most of her original research on the study of foraging behavior of hummingbirds, looking at their spatial, temporal, and decision-making abilities. After just a few summers, Sue and Andy's research teams had discovered that hummingbirds will preferentially use spatial information (distance and location) to locate a reward rather than visual cues (Healy and Hurly 1998), that these birds can use temporal information to time their return visits to flowers that refill at different time intervals (Healy and Hurly 2013) and that like humans, hummingbirds too will make relative choices rather than economically rational choices when given different concentrations of sugar solutions. Back in Edinburgh, Sue directed some of her attention to the study of sex differences in stress responses and spatial abilities in rats and humans, demonstrating that at least some of the observed sex differences in spatial abilities are due to differences in stress responses between sexes. Sue also started to do more theoretical work by reviewing the neurobiology comparative work and challenging, along with Professor Candy Rowe, the prevailing view at the time that larger brains enable more complex cognitive abilities (Healy and Rowe 2007).

In 2009, Sue took a joint position as Reader in both the Biology and Psychology and Neuroscience Schools at the University of St Andrews. At the University of St Andrews, Sue once again was one of the first people to establish the foundations of a new subfield in behavioral ecology by studying the cognitive abilities that birds use when building their nests. Although at the time,

behavioral ecologists regarded nest building a behavior "too complex" to be the result of learning mechanisms, Sue started to gather both field and laboratory evidence that birds do indeed use different types of learned information when building a nest (e.g., Guillette et al. 2016; Muth and Healy 2012). Sue and her team are also beginning to describe the neural structures underpinning this complex behavior (Hall et al. 2014). Sue continues to work with hummingbirds, now investigating how rufous hummingbirds use landmarks and their use of foraging routes (traplining) when visiting multiple locations. She has done so, while also being an active member of many scientific societies (in particular, the Association for the Study of Animal Behaviour, which owns the journal, *Animal Behaviour*, of which she is now European Executive Editor) and coediting a book dedicated to the study of avian cognition (ten Cate and Healy 2017).

Sue has made a significant contribution to the field of cognitive ecology by combining different approaches when studying animal behavior. Either when looking directly at the brain of animals or when studying their behavior in the laboratory and in the wild, Sue has successfully adapted the experimental dexterity of the comparative psychology tradition with the field of behavioral ecology. She has done so while showing younger men and women the practical rigor of science and the joy of a life studying animal behavior. Following her example, her female students have learned that like her male students they too should be confident and brave scientists.

Sue gave up her backpacking plans some time ago and now when travelling the world, with mostly books in her luggage, it is to give invited academic talks or to spend part of her summers in the Canadian Rockies, where long science or political talks can sometimes resemble a Fellini's dinner party scene. During the weekends, whenever she does not have her students over to her house to beat them at a game of croquet or to watch the Eurovision song contest, she enjoys gardening.

## Sustainable Forest Management

Yashpal Bhardwaj

Laboratory of Molecular Ecology, Department of Botany, Institute of Science, Banaras Hindu University, Varanasi, India

## Definition

The stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality, and their potential to fulfil, now and in the future, relevant ecological, economic, and social functions, at local, national, and global levels and that does not cause damage to other ecosystems.

## Introduction

In the last few decades, total forest area worldwide has decreased alarmingly from 5.9 billion hectares during pre-industrial area to just over 4 billion hectares, although the rate of deforestation and loss of forest from natural causes has slowed down from 16 million hectares per year in the 1990s to around 13 million hectares per year in the last decade (FAO 2011). The increasing global population has imposed the enormous pressure on forest resources which has obligated the necessity of its use in such a way that current demand meets the needs of the present without compromising the ability of future generations to meet their own needs (Du Pisani 2006). Nevertheless, the need to preserve natural resources for use by future generations had long been recognized.

The sustainability began to increase in importance and acceptance at the end of the 1980s and at the beginning of the 1990s. During early 1990s, the Brundtland Report “*Our Common Future*” (1987) and the Conference on Environment

and Development (Earth Summit) held in Rio de Janeiro, Brazil, in 1992, accelerated and pushed the sustainability concept to the table of policymakers. The latter concept establishes the linkages among the ecological and socioeconomic concerns (Fig. 1) at different scales of management and for different time periods. Healthy forests and trees provide number of services relevant for agricultural production and family livelihoods, such as food, feed for livestock, fuel, material for construction, fiber, and other requirements. Ecosystem services that help regulate ecosystem processes are equally important and pivotal for sustainable agriculture, soil protection, nutrient recycling, water regulation, microclimate regulation, and climate change mitigation (Reed et al. 2017). The forests are home for larger part of biodiversity, including pollinators such as insects and birds (Klein et al. 2007), pest control agents (Karp et al. 2013), and provide habitat for living organisms that are key for soil fertility, including bacteria and fungi. SFM is the process of planning and implementing practices for the stewardship and use of forests and other wooded land to meet specific environmental, economic, social, and cultural objectives (Siry et al. 2005). It deals with the overall administrative, economic, legal, social, technical, and scientific aspects related to natural and planted forests. It may involve varying degrees of deliberate human intervention, ranging from actions aimed at safeguarding and

maintaining forest ecosystems and their functions to those favoring specific socially or economically valuable species or groups of species for the improved production of forest goods and services (Table 1).

Many of the world’s forests and woodlands, especially in the tropics and subtropics, are still not managed sustainably. Some countries lack appropriate forest policies, legislation, institutional frameworks, and incentives to promote sustainable forest management, while others may have inadequate funding and lack of technical capacity. Where forest management plans exist, they are sometimes limited to ensuring the sustained production of wood, without paying

**Sustainable Forest Management, Table 1** List of benefits provided by the forests in terms of ecological, social, and economic values

| Ecological                 | Social                        | Economic                |
|----------------------------|-------------------------------|-------------------------|
| Climate stabilization      | Recreational and leisure area | Timber                  |
| Soil enrichment            | Traditional uses              | Nonwood forest products |

| CO <sub>2</sub> sink       |                               |                         |

**Sustainable Forest Management,**

**Fig. 1** Sustainable forest management shares the environmental, economic, and social values

attention to the many other products and services that forests offer.

Criteria and Indicators

The outcome of the earth summit was the “Forest principles” – a nonlegally binding statement of principles for a global consensus on the management, conservation, and sustainable development which could not be agreed upon at the time. Later on, several different international processes and initiatives have developed criteria and indicators (C&I) as a framework for describing, monitoring, and evaluating progress toward SFM. The C&I can be used as tools that define, guide, monitor, and assess progress toward SFM in a given context. The overall aim of criteria and indicators is to promote more SFM practices, taking into consideration the social, economic, environmental, cultural, and spiritual needs of different stakeholders. Criteria define the essential elements against which sustainability is assessed, with due consideration paid to the productive, protective, and social roles of forests and forest ecosystems (Wijewardana 2008). Each criterion relates to a key element of sustainability and may be described by one or more indicators. Indicators are parameters which can be measured and correspond to a particular criterion. They measure and help monitor the status and changes of forests in quantitative, qualitative, and descriptive terms that reflect forest values as seen by those who defined each criterion. Prabhu et al. (2001) suggested seven attributes to improve the quality of indicators (precision of definition, diagnostic specificity, sensitivity to change or stress, ease of detection, recording and interpretation, ability to summarize or integrate information, reliability and appeal to users). Similarly, Dale and Beyeler (2001) established eight prerequisites to selection (ease of measurement, sensitivity to stresses on the system, responsive to stress in a predictable manner, anticipatory, able to predict changes that can be averted by management actions, integrative, known response to disturbances, anthropogenic stresses and changes over time, and low variability in response). Although several

criticisms have been launched against the C&I system (Gough et al. 2008; Prabhu et al. 2001), the popularity of the system is evident from the effort invested in its development in recent decades.

The first set of C&I was developed by ITTO (1992) for sustainable management of tropical forest. Since then several regional groupings of countries have worked together upon the process of generating and testing appropriate C&I to suit their own conditions. There are 11 international and regional C&I processes (listed in Table 2), which collectively involve more than 174 countries to produce national reports that assess their progress toward sustainable forest management (Linser et al. 2018).

For instance, the Montreal Process is geographically the largest, encompassing most of the world’s temperate and boreal forests, and 60% of all of the world’s forests develop seven frameworks for forest conservation and sustainable management. Based on the most common criteria of SFM of C&I processes, United Nations Forum on Forests (UNFF) developed the non-legally binding instrument on all types of forests adopted in 2007 by the UN General Assembly, specifying four global goals as well as seven thematic elements of SFM (Table 3). Thus, regional

and international sets of C&I for SFM provide a vital structure for monitoring, assessing, and reporting on forests and their management and fostering progress toward sustainability goals.

### Forest Certification

Forest certification was introduced in the early 1990s to address concerns of deforestation and forest degradation and to promote the maintenance of biological diversity, especially in the tropics (van Kootena et al. 2005). Initially pushed by environmental groups, it quickly evolved as a potential instrument to promote SFM. To date about 124 million hectares or 3.2% of the world's forests have been certified by the different certification schemes created over the last decade. Certification is the process whereby an independent third party (called a certifier or certification body) assesses the quality of forest management in relation to a set of predetermined requirements (the standard). There are certain differences between the C&I process and certification of forest in context to scale, purpose, use, and user groups (Table 4).

The certifier gives written assurance that a product or process conforms to the requirements specified in the standard. Forest certification was introduced as a market-based response to address public concerns related to deforestation in the tropics, resulting loss of biodiversity and the perceived low quality of forest management in areas where traded wood products are sourced from. After a slow start spearheaded by the Forest Stewardship Council (FSC), the situation has

**Sustainable Forest Management, Table 4** Major differences between C&I and forest certification. (Adapted from Rametsteiner and Simula 2003)

|    |                                      |                                                                      |
|----|--------------------------------------|----------------------------------------------------------------------|
| 1. | Criteria and indicators for SFM      | Forest certification                                                 |
| 2. | Mainly national level                | Sub-national level                                                   |
| 3. | Descriptive approach                 | Prescriptive (standards/requirements)                                |
| 4. | Mainly used for information sharing  | Used for establishing proof of sustainable or good forest management |
| 5. | Used by governments and policymakers | Used by market players                                               |

radically changed when other schemes have become operational by the end of the decade. The initiatives on forest certification have set out to tackle an immensely diverse field by using one single instrument across the globe and across all conceivable situations. The ability of the instrument to contribute to SFM and biodiversity maintenance is, however, widely unclear. Forest certification standards have been largely developed outside the established standard setting bodies, and private bodies operate schemes and programs. Many of the standards have been developed through a multi-stakeholder approach, and thus the characteristics of each standard are guided in large part by the composition of each standards development team. As continuous improvement is an inbuilt element in most certification systems, the further development of standards is destined to move toward better convergence of differences. In 1993, an initiative led by environmental groups, foresters, and timber companies resulted in the creation of the Forest Stewardship Council (FSC). Subsequently, other initiatives at international and national levels gave rise to many other schemes, e.g., the Programme for the Endorsement of Forest Certification (PEFC, previously termed Pan-European Forest Certification), the Canadian Standards Association (CSA), the Sustainable Forestry Initiative (SFI), the Chile Forest Certification Corporation (CERTFOR), and the Malaysian Timber Certification Council, among others. Although

forest certification began in tropical forests, the trend has changed, and the scheme is now carried out in boreal and temperate forests. Almost 90% of forests certified by the two major programs (FSC and PEFC) are located within Europe and North America. More than half (54%) of the forests in Europe (excluding the Russian Federation) have already been certified, and almost one third of the forest area in North America has been certified.

## Conclusions and Future Perspectives

Sustainable forest management is a need of the current world to address the issue of degradation and deforestation while increasing benefits to human society with taking care of future generation needs. Sustainable forest management is evolving with public awareness and scientific knowledge, and the sustainability concept must be revised to reflect the new reality generated by climate change, where a past reference point should not be considered. Therefore, C&I should be updated continuously to be able to cope with the climate change challenge and assess sustainability of changing ecosystems. Furthermore, harmonization of C&I processes would be the most desirable outcome, since this would improve the credibility of the schemes. Enhanced sustainable forest management will require better reporting and verification and more areas covered and enhanced implementation of sustainable forest management criteria and indicators in the future. Further progress in improving forest management worldwide also relies on gathering better information needed to monitor and analyze global forest trends. A mix of effective public policies and private markets will continue to be needed to help achieve global sustainable forest management.

## Introduction

Most people know swine only as its domestic form (*Sus scrofa domesticus*) or as wild boar

(*Sus scrofa scrofa*). Relatively little attention goes to the rest of a total of up to 18 species in the Suidae family. The same also applies to behavioral research: although members of the family of Suidae are distributed all over the Old World, ranging from Asia to Europe and Africa, most studies focusing on their behavior and cognition are conducted on domestic swine.

In public perception, swine do not have the best reputation regarding their cognitive capacity, and they are often perceived as dumb as well as voracious and dirty. In contrast, fairy tales and fables, such as the Three Little Pigs or Animal Farm, depict swine as smart and intelligent enough to outwit potential predators or liberate themselves from the tyranny of their human masters.

In real life, swine have successfully adapted to various climatic and vegetation zones and exhibit a high foraging flexibility that is reflected in their omnivorous dietary spectrum. Their mixed diet makes it necessary for them to recall food distributed in patches that vary in spatial location but also in time. Swine are very social animals, forming long-lasting family bonds, and exhibit fission-fusion dynamics. All in all, these ecological and social circumstances require high brain processing power.

First investigations on the learning abilities of domestic swine date back to more than 100 years ago, and operant learning in swine was intensively examined in the late 1960s and 1970s (e.g., Wieckert and Barr 1966). Starting 20 years ago, questions on swine's cognitive capacities gained increased attention, and research began to examine their ability to remember food patches, solve problems when dealing with hard-to-access food, and recognize and discriminate between familiar and unfamiliar individuals (e.g., Gieling et al. 2011). The increased interest in their cognitive abilities is, on one hand, based on the fact that swine are physiologically more similar to humans than rodents are; therefore, domestic swine are increasingly used as a model organism in neuroscience and biobehavioral research. On the other hand, insights into the cognitive capacities of swine can be used to improve the welfare of this intensively kept farm animal by designing

methods to enrich their environment (Puppe et al. 2007).

Research on swine cognition has mostly been conducted on domestic swine, but given that all swine species are social and occupy a similar ecological niche, we can assume that conclusions drawn on domestic swine will likely apply to other species of swine as well.

## Swine as Discrimination Learners

Swine can learn to discriminate between two simple geometric black-and-white stimuli but seem to be unable to transfer this skill to discriminate between images of faces of familiar conspecifics (Gielsing et al. 2012a). In addition, swine showed slow visual learning abilities for the presented symbols compared to other species. Given their rooting foraging style, one would expect them to perform better in discrimination tasks that include olfactory or haptic cues. Indeed, when mini pigs were trained to discriminate between food extract odors, they were able to use visual or olfactory cues, in addition to spatial cues, to navigate in a new environment and to find a previously rewarded container (Croney et al. 2003).

## Swine as Spatial Learners

Swine, if allowed, feed on a very flexible diet, opportunistically exploiting a vast number of food sources. Thus, they do not only have to recall which patches they already exploited but also when they did so, because several food sources replenish over time. Therefore, it should not be surprising to find cognitive capacities that are well adjusted to their foraging ecology. Indeed, domestic swine are exceptionally good at using spatial information to find new food sources and to remember locations they have previously visited. Mendl and colleagues (1997) found that swine rapidly learned to find hidden food in a spatial memory task. Twice-daily, the researchers baited several food locations. The swine were able to find food regardless if the delay between visits was several minutes or several hours. Subjects

**Swine Cognition, Fig. 1** Test subject in a spatial holeboard task (Photo Ivar Pel, Utrecht University). This task measures spatial working and reference memory in swine and other animals

readily learned how to return to a location where they had recently fed, i.e., following a so-called “win-stay” strategy that might be an advantage under husbandry conditions due to the repeated provision of food at the same place. However, when given the opportunity, swine show a preference for a “win-shift” foraging strategy, i.e., avoiding locations where they have recently found food (Laughlin and Mendl 2000).

An excellent approach to demonstrate the spatial learning abilities of swine is their performance in a spatial holeboard task (see Fig. 1). In this task, multiple potential food locations are presented to subjects at a time, but only a small amount of them are baited with a reward. Here, domestic swine show very high scores in their reference (remembering where to find food) and working memory (avoiding revisits of baited locations) (Gielsing et al. 2012b). Notably, their performance in spatial learning tasks was affected by the level of environmental complexity and the number of stressful disruptions after initial learning, indicating an impairment of otherwise excellent spatio-cognitive abilities due to decreased welfare (Mendl et al. 1997).

## Swine as Problem-Solvers

The ability of swine to solve novel problems and understand causal relationships has been less investigated. Given their flexible diet and their

particular feeding habits, it should nonetheless come as no surprise to find cognitive abilities that enable them to adapt quickly to new foraging situations. One way to relatively easily assess physical problem-solving abilities is the administration of an object-choice task (see Fig. 2). Here, individuals can choose between two or more hiding locations (e.g., cups), while only one of the locations contains a reward. By providing specific indirect cues to the subjects when manipulating the cups (i.e., by lifting or shaking of the unbaited cup), subjects can potentially infer the position of the reward by using the causal relationships between the reward and the cup (i.e., an empty space below a cup or not hearing a noise while the cup is shaken indicates that the reward is in the other location). Swine were able to infer the correct location after seeing the empty cup lifted, but they did show difficulties when confronted with an empty shaken cup (Nawroth and von Borell 2015). Thus, swine seem to be able to understand some causal relationships behind the information provided and the reward in these tasks, although rapid learning might offer an alternative explanation. Nonetheless, these results provide support for their rapid adaptation to new foraging situations.

As mentioned above, swine perform well in object-choice tasks in which they have to

comprehend that food is hidden in one out of two or more potential baiting locations. This suggests that they exhibit at least a rudimentary level of object permanence. However, their ability to follow more complex movements of hidden objects still warrants further investigation.

There is not a lot known on the numerical competence of swine. Domestic swine have been shown to distinguish between different quantities of food (Held et al. 2005), while the mechanisms behind these discrimination abilities remain unclear. There is also little known on the ability of swine to use tools. However, wild boar kept in zoos have been observed using water to wash the dirt off of potatoes and other food (Sommer et al. 2016), providing a first case for rudimentary tool use in swine. On a final note, given that swine rely more on olfactory and acoustic rather than visual cues when foraging, paradigms relying on smell and sound might be a more promising attempt to uncover their problem-solving skills (Croney et al. 2003).

## Swine as Social Animals

In general, swine are highly gregarious animals, forming stable social hierarchies. Wild boar and feral domestic swine form matricentric groups of

**Swine Cognition, Fig. 2** Setup of an object choice task for domestic swine (left, © by FBN) and wild boar (right, taken from Albiach-Serrano et al. 2012)

older females with their offspring, while young males often form bachelor groups. Adult males remain solitary and only join the females during the mating season.

### Differentiation of Conspecifics

Living in groups requires good discriminatory abilities to differentiate between group and non-group members. Thus, it is not surprising that domestic swine can not only differentiate between familiar and non-familiar conspecifics but also between group members through the use of visual, auditory and olfactory cues (McLeman et al. 2005). In term of visual cues, they appear to use primarily body size and body features to distinguish between familiar conspecifics. Head only cues of familiar conspecifics do not seem sufficient for discrimination learning (Gieling et al. 2012a).

### Social Learning

Due to their flexible diet, one would expect information transfer from adult swine to piglets. For young swine, it would not only be an advantage to learn what to eat but also how to acquire and process particular food sources. Indeed, it has been demonstrated that domestic piglets are capable of learning what food to prefer from observing the feeding behavior of their mother (Oostindjer et al. 2011). They can also learn how to solve a simple puzzle from kin. When piglets watched adults moving a door to either the left or right side, they tended to open the door in the same direction (Veit et al. 2017). Information transfer between adult swine or social learning from humans has not been investigated yet.

### Swine and Humans

Humans have domesticated swine for as long as 9000 years (Giuffra et al. 2000). But unlike dogs and horses, domestic swine have not primarily been bred to cooperate with humans. However, one would expect that these animals also cognitively adapted to their new domestic environment, leading to improved recognition of and communication with humans. Thus, it is no surprise to find that swine are able to tell handlers apart, mainly relying on the body height and upper

torso of the human (e.g., Koba and Tanida 2001). When piglets are confronted with two humans, of which only one paid attention to them, they preferred to approach the attentive one in anticipation of a reward (Nawroth et al. 2013). This indicates that piglets realize when they are being watched – and who is watching them.

Domestic piglets can also learn and attend to some forms of human communication; for example, they can use a variety of pointing cues and are also able to utilize the body and head orientation of a human to locate a hidden reward in an object-choice task (Nawroth et al. 2014). Interestingly, wild boar will follow human pointing gestures as well (Albiach-Serrano et al. 2012, see Fig. 2). Domestic dogs solve this kind of task by using the referential information conveyed by those gestures. However, for the piglets and wild boar, it might be that they are simply following the pointing gestures by relying on stimulus enhancement. Thus, it is not clear yet whether they can comprehend the referential and intentional nature that is usually included in human communicative cues.

## Other Cognitive Phenomena in Swine

### Time Perception/Mental Time Travel

Swine do remember when food sources have been visited and show indications of episodic-like memory, with the latter requiring the simultaneous recall of the what, where and when/which aspects of an event. In an object recognition test, swine identified the less familiar of two object/location/context configurations. Since configurations only differed in familiarity if all aspects were remembered simultaneously, swine recalled the what/where/which aspects of the configuration (Kouwenberg et al. 2009). Given that swine estimate time intervals in the range of days (Fuhrer and Gygax 2017), it is likely that they can also encode the “when” aspects of events.

### Self-Awareness/Mirror Test

Although swine belong to a set of species that are able to use a mirror to obtain information from

their environment (Broom et al. 2009), there is no evidence that they can recognize themselves in a mirror, i.e., pass the renowned mark test that was initially developed for primates. However, the absence of evidence for mirror self-cognition does not necessarily imply the evidence of absence. As previously stated, swine rely heavily on olfactory cues, so using different modalities than visual ones might be a promising method for further investigations.

### Theory of Mind

Swine are highly competitive foragers, relying on food sources distributed in patches. Therefore, it is not surprising that more dominant swine readily start to scrounge on subordinate individuals by following them to food patches the subordinates have discovered (Held et al. 2002). To counter this exploitative behavior, it seems adaptive for swine to be aware of the presence and attentive states of other individuals. Using an informed forager paradigm, Held and colleagues (2002) showed that the approach time of a subordinate but knowledgeable swine to get to a baited container depends on the body position of the dominant but ignorant (in terms of the baited location) conspecific. Overall, subordinates were more likely to show food-directed behavior when the chance of arriving at the food source ahead of the dominant subject was higher. Intriguingly, the subordinates adjusted their foraging behavior based on the individual they were foraging with, i.e., counter-exploitation behavior was only shown with dominant subjects that already scrounged on the subordinates in previous foraging trials (Held et al. 2010). In another experiment, swine were trained to follow one of two companions: one of them could observe a baiting procedure and thus knew about the location of food, while the other could not observe the events and lacked this knowledge. Most test subjects did not follow any of the two companions, probably to avoid competitive and aggressive behavior. Nonetheless, one swine followed the “knowing” individual significantly more often than the “unknowing” individual, indicating sophisticated abilities of what others can or cannot see or know (Held et al. 2001), a trait previously attributed to primates and some corvid species.

### Swine Cognition and Animal Welfare

Swine cognition is not only relevant in terms of comparative psychology or translational biomedical research but also for applied aspects of the innovative implementation of their cognitive processes in husbandry systems. Right now, there are more than one billion domestic swine raised worldwide, and their housing conditions range from being intensive indoor conditions to extensive outdoor conditions. Therefore, knowledge on the cognitive abilities of swine becomes increasingly important for the development of practically useful applications that can be integrated in the housing environment to avoid boredom and frustration, and thus, improve animal welfare. For example, enriching the housing environments with only simple changes (e.g., use of straw, peat or manipulative objects, or more structured space) can improve the learning abilities of swine in operant, maze or discrimination tasks (e.g., Grimberg-Henrici et al. 2015).

Today, it is more and more accepted that the implementation of cognitive challenges into the normal housing routine can serve as a form of cognitive enrichment, and therefore offers a way to improve how swine cope with their husbandry environment (Puppe et al. 2007). Indeed, a cognitive enrichment system using food-rewarded learning with discriminatory and instrumental tasks (Ernst et al. 2005, see Fig. 3) has been shown to improve welfare-related behavioral patterns (e.g., reduced abnormal behavior, decreased fearfulness), while also demonstrating enhanced wound healing, altered gene expression in reward-sensitive opioidergic systems in the brain, and seemed to evoke positive emotions in swine (Zebunke et al. 2011). Considering these results, it is an obvious conclusion that allowing swine to use their cognitive talents under captive conditions appears to be an influential way to enhance their welfare.

Similar to findings in other species, the emotional state may affect the cognitive processes in swine. Consequently, animal welfare scientists are interested in measuring and enhancing the cognitive-affective state of animals living in captive conditions. One promising approach to do this is by testing cognitive bias, for example, in a

**Swine Cognition, Fig. 3** (left) Cognitive enrichment through operant reinforcement: Swine in a pen with call feeding station (Ernst et al. 2005), equipped with Polar belts for heart rate measurements. (right) Cognitive bias test setup: Piglets were taught that a reward will be found on the left side, and they got slightly punished when they

approached the right side. In probe test trials, a container was positioned in the middle, and latency times of the piglets' approach were measured as an indicator of positive or negative expectations (both photos © FBN Dummerstorf)

spatial judgement task specifically modified for the use with swine (Düpján et al. 2017). Using this paradigm, it has been shown that structural enrichment seems to affect the animal's affective-emotional reactions, leading to more optimistic judgements in this task (Douglas et al. 2012). Cognitive stimulation, as a particularly effective method of enrichment, is likely to impact similarly on swine affective states (Zebunke et al. 2011).

## Conclusion

Our knowledge of the cognitive abilities of swine is largely based on research on domestic pigs. So far it has been shown that swine have advanced skills in spatial learning, memory and social cognition, and they show at least basic levels of time perception and awareness. Allowing them to use these cognitive skills appears to be an important way to enhance their welfare under restricted housing conditions.

## Swine Communication

R. Cyril Roy<sup>1</sup> and Selvi Roy<sup>2</sup>

<sup>1</sup>Prairie Swine Centre, University of Saskatchewan, Saskatoon, Canada

<sup>2</sup>University of Prince Edward Island; Atlantic Council for International Cooperation, Charlottetown, PEI, Canada

Pigs use a rich repertoire of vocalizations, body postures, and chemosensory mechanisms to communicate with conspecifics (social cognition) and also with other species including humans. Even though vocal communication may be the most explicit, specific postures and behaviors such as play fighting and chemosensory mechanisms of communication are equally important for pigs to maintain social hierarchy and successful reproduction. Different types of vocal calls help pigs to discriminate between other members of its group and transmit information about the environment they are in. Vocal communication contains information on motivation and emotion of the sender (Chan et al. 2011) and also their identity, location, and body size (Špinka 2017). Behaviour and posture-based communication are used by pigs to express certain emotional states to other conspecifics. Behavioral expressions such as play fight and tail postures (Groffen 2012) have been identified as good indicators of emotional state of the pig, and hence there has been an effort to validate these behaviors

to assess welfare. Pigs use olfactory system (chemosensory mechanism) for reproduction similar to many other mammals (Dorries et al. 1997). Also, chemosensory communication is used by pigs for reproduction, which helps in the survival of the species in the wild and also helps us run a profitable pork industry by breeding domestic pigs. Male pigs emit specific odor, which triggers a hormonal mechanism in gilts to attain puberty and also triggers reproductive cycle in sows. Last but not the least, there are some communication methods that are still not fully understood. For example, pigs tend to display decreased locomotion and freezing when stressed and when they see a conspecific in distress (Goumon and Špinka 2016). Such responses also have husbandry and welfare implications. This entry presents the diversity of swine communication with a view to better understand their behavior to improve pig health and welfare in a farm, feral, or wild environment.

## Vocal Communication

The pig vocal ethogram can be described as a set of highly flexible call types connected through an acoustic continuum (Tallet et al. 2013). Domestic pigs of today, even though highly selectively bred for a profitable pork production, still show most vocalization repertoire of their wild ancestors. Descriptions of vocalizations identified in wild and feral pigs by Allwin et al. (2016) are useful to understand the functional aspect of different vocal calls of domestic farmed pigs. In the wild, loud grunts are associated with danger, male to male interaction for dominance, and for warning the piglets. Squeals are indicative of some painful situation or some submissive gesture. Wild pig vocal repertoire also had loud grunts associated with separation from social group, a lower-pitched grunt while displacing another pig during feeding, and nursing-associated grunts. Marchant et al. (2001) studied the vocal repertoire of domestic pigs using social isolation and approach to human and suggested that short single grunts are associated with investigative behavior, long

single grunts associated with contact call, and squeals associated with higher level of arousal. Schrader and Todt (1998) found correlation between high-pitched squeals and stress hormones thereby providing evidence to the notion that vocalization can be used to assess stressful situations in domestic pigs. Other vocalizations recorded and studied are piglets barking when they are surprised (Chan et al. 2011) or when they play (Newberry et al. 1988), screaming in painful situations (Marx et al. 2003), croaking during naso-nasal contacts with mother (Illmann et al. 2001) and grunt when briefly isolated (Fraser 1974).

Vocal communication is used by pigs to express their emotional states (Düpjan et al. 2008; Leliveld et al. 2017) negative such as hunger, distress, fear, and aggression and positive such as playfulness. Hunger vocalizations (squeals and screams) can be noticed in intensively raised pigs, particularly in gestation sows which are on restricted diet at the time of feeding. Piglets make similar scream, squeal, and some grunts when they are hungry and ready to feed (Appleby et al. 1999). The hunger squeals made by piglets at the udder may also attract the remainder of the piglets before the sow make the feeding calls. Continued squealing by piglets during feeding often causes the sow to roll over further to make the lower teats available to the piglets.

Nursing sows have specific vocal communication to indicate the piglets to feed. The sow's pattern of vocalization (grunts of varying intensity) is related to the different phases in which the piglets are in the feeding routine. The rate of grunting by the sow does not vary during the initial phase of feeding by piglets but increased substantially in the later stages of feeding (Ellendorff et al. 1982). These are soft rhythmic grunts, which are repeated in a rapid series, and are made by nursing sows at the beginning of and during nursing of her litter of piglets. The function of these feeding-associated grunts is to solicit the litter to begin and continue nursing. The feeding call of nursing sows is given in response to the behavior of the piglets which first start to squeal. Nursing sows then vocalize

the feeding call which attracts all the piglets to feed.

Fear in pigs elicits a characteristic alarm call or bark, heard when disturbed suddenly which has the effect of sending all young piglets running. Barking could also be witnessed when entering a room suddenly surprising young adult pigs or adult pigs in a hog barn. Barking has not been observed in piglets younger than 1 week. Chan et al. (2011) found that differences in acoustic morphology of barks enable domestic pigs to discriminate between barks of adult sows and juveniles, with former evoking a stronger response.

Warning calls by sows with piglets can be different from bark vocalization. The most distinctive warning call is given when the nursing sow moves before standing up and continues while standing up. This call seems to be a mild version of the threat snort. The sound is a grunt with sharp exhalation. The signal causes the piglets to walk from the sow and stand together a few feet away. Postpartum nursing sows can reinforce this behavior in piglets by nudging them away and may even appear to savage them by taking them in her mouth before thrusting them away. If the threat interpretation of this call is correct, the ambivalence displayed by the piglets is of considerable significance since the movements of the sow constitute the greatest hazard to piglets in their first few days.

Squeal is typically a distress or submission vocalization made during both the intraspecies and interspecies interactions of wild pigs. This call can be made by any animal, but is more commonly heard among immature or subordinate individuals. Marx et al. (2003) classified pain-related vocalization in piglets depending on the strength of spectrograms into squeals and screams. According to that classification, squeal had highest-frequency sounds, and scream are medium-frequency sounds. Both squeal and screams are loud, high-pitched piercing vocalizations repeated continuously until the threat ceases. When painful husbandry procedures such as castration are done without surgical anesthesia, pigs of all ages squeal. Squeal vocalization is also produced by piglets when they get caught

inadvertently under the mother after the first few days after parturition. These vocalizations reflect the urgency of the situation, thus inciting the mother to intervene, with louder, louder and higher screams signaling higher danger for the pig. In life-threatening situations, such as castration, crushing, and arms and fighting, piglets produce long, high-pitched squeals and screams. More precise information may be conveyed leading the mother sow to react appropriately according to the situation. She may respond with aggression against the predator or by standing up in the case of crushing or by interrupting the nursing in the case of severe fighting between piglets.

When the piglets first walk a yard or so from the sow, they start to give their location call. This is a soft snore repeated continually. The sow responds by a similar and more powerful call, which generally has the effect of attracting some other piglets to her head. Among older litters, particularly at night, when the pigs leave the sow one by one to walk to the feed trough, they give this location call whenever walking alone. The significance of this location call seems to be to maintain communication with other pigs whenever they are not in close proximity to each other.

## Communication Through Postures and Body Language

Pigs use a range of postures, specific behaviors including body movements, and facial expressions (grimace score in piglets) to communicate feelings, such as contentment, hunger, pain, fear, and aggression. Grimace score which is based on facial expression has been increasingly used to assess pain in piglets when pain mitigation strategies are implemented following regular husbandry procedures such as castration (Viscardi et al. 2017). Wild and feral pigs use body posture-assisted visual signals such as bristle rising, ear position, tail movement, and arching the back to express aggression. In domestic pigs, this communication has substantially diminished, probably due to morphological

changes that prevent the signals from being clearly displayed. Raising of bristles is to warn the predator and increase the appearance of ferocity of the prey. Arching of the back is also to offer the image of ferocity by making the body appear taller and bigger. Forward position of the ears is indicative of keenness, and listening. Backward position of the ears is communicative of fear and suspicion. The backward ear leaning may tend to give the animal an aerodynamic flight position either to get into a fight or to flee the fright-generating situation. Tail position and movements are also used for communication. Tail low or between legs can be understood as a sign of fear (Noonan et al. 1994). Curled tail is indicative of a positive emotional state, while hanging tail is characteristic of a neutral state, and wagging tail is expressive of a negative emotional state such as restlessness (Groffen 2012).

Body movements associated with communication are teat massaging by piglets, teeth clacking by wild pigs, nosing, rubbing, and tail movements. Tactile communication in the form of teat massaging is used by piglets during nursing to trigger milk ejection. Piglets also communicate their levels of hunger through the length and intensity of teat massaging. Teeth clacking is not truly a vocalization but an aggressive expression produced by tooth impacts primarily the canines, through rapidly champing of the jaws. Mostly heard among mature males during aggressive interactions, it can consist of either single or a few multiple mouth impacts. This functions as a warning or threat during aggressive encounters between conspecifics or against potential predators.

Casual, slow, unobservant, and relatively quiet body movement communicates that the environment is without any stressors. When environmental stressors are absent, piglets often exhibit playful behavior such as sprinting, galloping, and spinning around. Play behavior in young remains a topic of considerable interest for ethologist who are interested in improving the welfare of intensively raised pigs because of the positive emotion attached to play. Play has also been proposed as an indicator of animal welfare as it is drastically reduced by bad

husbandry practices, fitness challenges, injury, and pain. Lawrence (1987) proposed that hence play behavior is a luxury or elastic behavior which is performed by animals only when their proximate needs are met, it could be a good indicator of well-being. Play behavior in pigs can be locomotor (running), object-directed, and social play (Blackshaw et al. 1997). The behaviors that are recognized as play in pigs have some resemblance to adult behaviors (e.g., running; play fighting) but at the same time are recognizably different from being performed in an exaggerated, energetic, and repetitive manner (Newberry et al. 1988).

When pigs are anxious or fearful, their movements are quick and erratic, often accompanied by loud and shrill squealing. Their gaze is no longer unobservant but is directed toward the person or object that is the source of anxiety and fear, and their posture is alert and forward-facing. Lack of body movement and freezing have also been considered an important form of communication. As Goumon and Špinka (2016) report, distress is expressed through reduced locomotion and freezing, when pigs are exposed to conspecifics in stressful situations such as being restrained.

## Olfactory Communication

Olfactory communication in animals is a process by which chemical signals are generated by a sender and transmitted to a receiver, who, by means of adequate receptors, can identify, integrate, and respond behaviorally and physiologically to the signal (Eisenberg and Kleimann 1972). Pigs use olfactory channels for mating and general survival. In the olfactory realm, adult males actively advertise their status by producing chemical compounds, two of which are the sources of the unpleasant taint sometimes present in pork from non-castrated post-pubertal males.

Aldosterone is one of the chemical compounds produced by the testes and is present in the saliva, urine, and the preputial glands and gives the smell of urine in the meat. This compound triggers the standing reflex in estrous sows and can advance the puberty of gilts. The olfactory

system of the female is five times more sensitive to aldosterone than the male system. The second chemical compound is skatol. This compound emanates a smell similar to that of feces. It is controversial that pigs can communicate danger using smell. Whether or not pigs can detect smell and communicate in non-vocal ways for social purposes are debatable. It has been hypothesized that pigs use olfactory cues to communicate with humans (Hemsworth et al. 1986). However, the range of olfactory cues are less likely to be detected by the human olfactory range and current assessment methods.

## Conclusion

Vocal, behavioral, and chemosensory communication among pigs represent their social cognition and affective states. Interest in understanding pig communication has increased over the years partly for improving how we relate to pigs especially when we interact with them in close proximity, due to the potential of increasing welfare, for increasing productivity (e.g., through better piglet and pig feeding), and also for enhancing the quantity and quality of pork. In pig production and transport facilities, excessive use of the electric pod, for example, can lead to increased incidence of stressed and non-ambulatory pigs. Similarly, insensitive and rough handling can result in higher incidence of freezing and reduced locomotion. With greater understanding of pig communication, better training can be offered to individuals working in swine production and transportation facilities. Overall, enhanced understanding of pig communication can be translated into better training for people who are involved in the hog industry. And in turn, proper animal handling plays a key role in the health and welfare of the pig as well as the quality of the final product.

## Taxonomy and Domestication

Domestic pigs (*Sus scrofa*) belong to the mammalian order Artiodactyla, derived from the Greek word *artios* meaning complete or even-numbered and *daktulos* meaning finger or toe (Young 1981; Nowak 1997). This large order of even-toed ungulates is made up of three suborders which differ based on teeth structure, metatarsal or metacarpal fusion, and digestion. These suborders are Suina (pigs and peccaries), Tylopoda (camels and llamas), Ruminantia (cattle, antelopes, deer, and giraffes), and Cetancodonta (hippos, dolphins, and whale) (Young 1981; Nowak 1997). Within the Suina suborder, there are two living families: Tayassuidae (peccaries) and Suidae (pigs). There are currently 19 living species split into 6 genus in the Suidae family: 3 species of deer pigs (*Babyrousa*), the giant forest hog (*Hylochoerus meinertzhageni*), 2 species of warthogs (*Phacochoerus*), the pygmy hog (*Porcula salvania*), 2 species of bush pigs (*Potamochoerus*), and 10 species of the *Sus* genus (Ruvinsky and Rothschild 1998). Species in the *Sus* genus share a common ancestor approximately 5 million years ago, and hybridization is possible among the species (Giuffra et al. 2000; Larson et al. 2005).

The domestic pig originates from the Eurasian wild boar (*Sus scrofa*). Archeological record and mitochondrial DNA research suggest that the species was domesticated approximately 8000–10,000 years ago in two separate locations: in the Mekong valley of China and in the region of modern-day Turkey (Larson et al. 2005; Minagawa et al. 2005; Giuffra et al. 2000; Jing and Flad 2002). The Chinese and European *Sus scrofa* breeds diverged approximately 2000 years ago (Paszek et al. 1999). Selective breeding of *Sus scrofa* resulted in a domestic breed with a reduced

fear of humans, to allow for easy and safe handling, as well as an increase in body size, litter size, and growth rate (Price 1984). For example, an adult wild boar can reach up to around 230 kg (Sweeney et al. 2003; Bieber and Ruf 2005), while a modern adult pig may weigh more than 350 kg (Whittemore 1994), and a wild sow may have a litter size ranging from 2 to 6 piglets (Sweeney et al. 2003), while a modern domestic sow can produce an average of 10–12 piglets per litter (Setchell 1992).

## Expansion of Domestic Swine

Domestic or feral pigs can be found on all continents, except Antarctica, including many oceanic islands (Waithman et al. 1999; Hanson and Karstad 1959; Graves 1984). The ease with which domestic pigs have been propagated across the globe may be due to the fact that they reach sexual maturity at a young age, females give birth to large litters twice a year, and the animals can be fed human food-waste (e.g., brewing and distillery by-products). In 1493, Christopher Columbus brought the first batch of swine to the New World in the West Indies. The first pigs to be brought to the North American continent occurred in 1593 when Hernando de Soto landed in Florida (Towne and Wentworth 1950; Porter 1993). Starting in the seventeenth century, early colonial settlers, Native Americans, and game hunters have promoted the distribution of pigs across the United States (Seymour 1970; Mayer and Brisbin 1991). Feral populations of domestic swine can be found from Texas east to Florida and north to Virginia and in California, Hawaii, Puerto Rico, and the Virgin Islands (Sweeney and Sweeney 1982; Mayer 2009). Escaped domestic pigs in the eighteenth century have led to large feral populations in Australia and New Zealand as well (Tisdell 1982).

## Social Structure and Home Range

The social structure of *Sus scrofa* is characterized by solitary adult males and matrilineal groups of females and piglets (called “sounders”). Sounders

are composed of two to four sows, often genetically related, with their litters and are led by a dominant sow throughout a shared home range (Gabor et al. 1999; Gonyou 2001; D'Eath and Turner 2009). Older and larger sows tend to be more dominant than subadults and juveniles in a sounder (Mauget 1981; Gonyou 2001). Through frequent nose-to-body and nose-to-nose contact, swine use olfactory cues to identify other individuals (Kristensen et al. 2001; Mendl et al. 2002; Stookey and Gonyou 1998), which is fundamental in maintaining their social hierarchy. The social order in a sounder may be maintained through subtle behaviors, such as a subordinate individual averting the gaze of a dominant and overt aggression like reciprocal fighting (i.e., parallel-pressing; Jensen 1980).

Sounders engage in synchronized activities (e.g., foraging and resting) led by dominant sows and engage in cooperative defense of their piglets against predators (Mauget 1981; Graves 1984). Given that pigs are opportunistic omnivores, their home range size depends on the features of their environment, such as food availability and population density. The average home range size for a sounder varies from a few hundred to several thousand acres and may overlap with neighboring sounders (Kurz and Marchinton 1972; Singer et al. 1981; Graves 1984). Because pigs do not have functional sweat glands, they are sensitive to high temperatures and are most active at dawn and dusk (i.e., crepuscular) (Sweeney et al. 2003).

Juvenile pigs remain within their dam's home range from lactation into subadulthood (Cousse et al. 1994). While female piglets remain with their natal sounder once they reach sexual maturity around 8–10 months (Frädrich 1974), male piglets disperse from their sounder before they reach sexual maturity at around 6–10 months of age (Frädrich 1974; Truve and Lemel 2003; Gabor et al. 1999). This strategy limits inbreeding within a sounder by the polygynous boars (Gabor et al. 1999). Occasionally, smaller groups of female pigs split off from their natal sounder to form a new sounder with a new social hierarchy (Gabor et al. 1999). Upon leaving their natal sounder, young boars form small bachelor groups and roam through new home ranges. The boars

become gradually solitary as they mature, foraging for food and searching for new sounders during mating season (Graves 1984; Gabor et al. 1999; Frädrich 1974; Mauget 1981).

## Mating

The mating season for wild and feral pigs begins in autumn and, given that gestation is approximately 115–118 days, peak farrowing activity during the winter through early spring and occasionally in the summer (Mauget 1981; Sweeney et al. 2003; Taylor et al. 1998). Wild and feral sows often show seasonal anestrus during the summer, which may be due to the change in day-length (Delcroix et al. 1990; Tast et al. 2002). Almost as soon as female pigs reach sexual maturity, they begin to breed, but younger males often do not mate until they are able to compete successfully with older boars (Mauget 1981; Sweeney et al. 2003; Taylor et al. 1998). Sexually mature boars do not interact with sows outside of the mating season and rarely interact with each other except for during competition for female access during the mating season (Kurz and Marchinton 1972; Gonyou 2001).

Sexual pheromones (called androsterone) released by the boar's foamy saliva help to stimulate the synchronization of estrus among sows of a sounder (Mayer and Brisbin 1986; Claus et al. 1994). A boar will nudge a sow with his snout and produce rhythmic grunt sounds to determine if she is receptive to mating. In order to prepare for mounting behavior associated with mating, a sow in estrus will display a rigid, motionless standing posture in response to the boar, especially when pressure is applied to the rear of her back (Fraser 1984; Mauget 1981). When competing for access to a female in estrus, males will walk in circles near each other and then engage in shoulder-to-shoulder pushing, head knocks, and reciprocal biting (Frädrich 1974; Barrette 1986). Although mating competition among males does exist, females often mate with more than one male during the breeding season which results in litters of mixed paternity (Fraser et al. 1995).

## Farrowing and Weaning

Toward the end of gestation, pregnant sows will become more solitary and keep a distance from other sows in their sounder in search of a location to build their nest (Mauget 1981; Stolba and Wood-Gush 1989). Sows begin to collect vegetation and small branches to build a nest approximately 1–3 days prior to giving birth (called “farrowing”) (Frädrich 1974). After partition, sows stay with their piglets at the nest site for the first 2 weeks before rejoining the sounder (Mauget 1981; Csermely 1994). Neonatal piglets are highly dependent upon the sow for nutrition, ambient body heat for temperature regulation, and protection from predators (Hartsock and Graves 1976). Piglets use tactile, vocal, and olfactory cues from the sow to locate the udders for nursing (Horrell and Hodgson 1992; McBride 1963). Piglets are able to discriminate odors from their nest as early as 1 day old and can identify their mother’s vocalizations soon after (Horrell and Hodgson 1992; Walser 1986).

Piglets will engage in scuffling in the first few days of life while competing for access to teats during nursing (Algers 1993; Fraser and Jones 1975; McBride 1963). As they develop, piglets will engage in rough-and-tumble play with their littermates and with other piglets by mimicking the fighting posture of adult swine (parallel-pressing) and will start to explore their environment away from the nest (Dobao et al. 1985; Newberry and Wood-Gush 1988; Jensen and Redbo 1987). The sow will use vocal communication, such as short rhythmical grunts, when leading the piglets away from the nest, prior to lying down in a nest, and to call the piglets at nursing (Frädrich 1974; Newberry and Wood-Gush 1986). The dominant sow of a sounder will often start vocalizing as her milk is let down, and this leads to a synchrony of vocalization and lactation within a sounder (Horrell 1997; Newberry and Wood-Gush 1985). Given that piglets within a sounder are most likely genetically related to all sows in the herd, cross-suckling among the litters may occur (Fraser et al. 1995). Often, most sows within a sounder will respond to a piglet distress call

(e.g., loud squeal) when attacked or captured by a predator (Frädrich 1974).

Piglets will increase the proportion of solid food in their diet at around 4–5 weeks old and will be completely weaned from sow’s milk around 14 weeks (Jensen and Recen 1989; Newberry and Wood-Gush 1985). Piglets will follow the roaming path of the sounder as they mature, exploring their environments by digging and rooting up objects to test for edibility (Studnitz et al. 2007; Wood-Gush and Vestergaard 1989). As the male piglets reach sexual maturity, they explore the environment beyond the bounds of their natal home range, while female piglets continue to follow their dams in search of food.

## Commercially Reared Pigs

Pigs have been under selective breeding pressure since being domesticated 9000 years ago (Giuffra et al. 2000). Several breeds have been developed that feature distinct phenotypical characters such as coat color, ear morphology, as well as combinations of traits that favor either maternal or carcass performance. Maternal breeds such as Yorkshire, Landrace, or Large White have been selected to produce large litter size and noted milk production. In contrast, carcass or terminal breeds such as Duroc, Hampshire, or Pietrain have been selected for fast growth and efficient feed conversion and to produce heavily muscled, high-quality carcasses. Today most commercially reared pigs are carefully planned hybrids of these different common breeds and genetically selected to meet the specific requirements for a variety of different uses for pigs.

## Social Structure and Home Range

Compared to their wild counterparts, most domesticated pigs are raised under more confined conditions and managed more intensively to meet the goal producing an affordable and safe source of animal protein for human consumptions. In most parts of the world, breeding sows are individually housed either in a gestation or a farrowing crate depending upon their stage of production (Pajor

2005; McGlone 2013). Such housing precludes social interaction as well as many other normal behaviors such as establishing a home range. However, social pressure is driving both legislative and consumer-based initiatives around the world to reduce the confinement of sows, especially during gestation (Lassen et al. 2006; Appleby 1999; Tonsor et al. 2009). Group sizes in such loose housing system can range from 6 to 250 sows and allow for the formation of a social hierarchy (Bench et al. 2013a, b). In the husbandry systems that use large groups (>40 sows), subgroup formation occurs as clusters of sows similar in size to that found in the sounders of wild pigs arise. These animals typically rest together in the same area of the pen as well as eat together and are in part defined by age of the sow (Den Hartog et al. 1993). Growing pigs are housed in groups and free to carry out more natural behaviors than their mothers. However, the habitat of these animals ranging in age from 3 to 24 weeks of age is often quite barren and devoid of any substrate that would allow these animals to pursue their behavioral needs to forage (da Silva et al. 2016).

## Mating

Gilts enter most sow herds at the time of puberty and are bred for the first time between the age of 6 and 9 months of age. Similar pigs in the wild exposure to boars and their pheromones induce puberty and help to synchronize estrus and subsequent breedings (Kekan et al. 2017). Mature sows exhibit lactational anestrus, that is, while nursing their piglets, follicular stimulation is inhibited, and the sows fail to exhibit estrous behavior. However, shortly after weaning, this inhibition is reversed and within 4–7 days postweaning most sows will be returned to estrus and are bred (van Wettere et al. 2017).

Today almost all commercially raised females are bred via artificial insemination. Fresh boar semen is delivered from specialized farms called boar studs where only male pigs are reared. Semen is regularly collected from the boars and diluted to with a physiological solution that serves

to promote the shelf life of the semen and extend the semen by diluting it to a minimum concentration of sperm cells required for to inseminate a sow. This effectively increases the number of sows that could be bred by one boar and reduces the number of boars that need to be maintained for breeding purposes (Knox 2016).

## Farrowing and Weaning

Gestating sows are moved into specialized facilities, often called farrowing rooms, around day 110 or 112 of their pregnancy. Most commonly within these rooms are individual pens for the mother and her newborn litter. The sow is confined within the pen by a stall or crate that limits her mobility. This requires that she lays down slowly to help minimize injuries or deaths that might occur if a piglet is in her way when transitioning from standing to lying down (Singh et al. 2017). A localized heat source is provided for the piglets as their thermal requirement at birth may be as much as 10 °C higher than the mother sow (Curtis 1983). Rarely is bedding or other substrates available to the sow prior to farrow, and this in combination with the confinement of the farrowing crate can result in the frustration of the sow's behavioral drive to nest build (Yun and Valros 2015).

Piglets are born into litters of 14 or more and typically lactate for 21–28 days before being weaned. Most sow farrow without assistance and farrowing takes several hours. In the absence of any complications, piglets are birthed about every 20 min (Van Dijk et al. 2005). Pigs rapidly establish a social hierarchy as well as a nursing order where individual pigs will defend and nurse from a particular teat for the duration of lactation (Hartsock et al. 1977; Scheel et al. 1977). Piglets may be moved from one litter to another, or cross-fostered, to ensure that the number of the piglets nursing matches the number of available functional teats for nursing. Otherwise the survival of these teatless pigs is compromised due to malnourishment (Edwards and Baxter 2015).

Upon weaning the piglets are typically moved to another facility dedicated to raising newly weaned pigs and mixing into larger groups

typically of about 25 pigs. Litter integrity is often disrupted as pigs are sorted by size and/or sex. In addition to the social stress of regrouping, piglets also face nutritional stress following weaning as they are required to transition from their mother's milk to solid diets comprised of different cereal grains (Campbell et al. 2013). Pigs typically remain in a so-called nursery for up to 8 weeks before being moved to another facility. As the pigs grow, more space is allotted to them to compensate for their larger static and dynamic space requirements. The majority of the pigs will spend another 10 or 12 week in a finisher before going to slaughter at about 5–6 months of age and weighing upward of 130 kg. These market hogs are the source of most of the pork meat consumed by human. Domesticated pigs have been selected for rapid growth as well as efficient conversion of feed into meat. Conversion rates continue to improve but are approaching a ratio of <3 kg of feed for every kilogram of weight gain. Such a feed efficiency is much better than beef cattle (7.5) but still less than poultry (2) or fish (1) (Tolkamp et al. 2010).

## Boars

The greater majority of male pigs are castrated at a young age to prevent the development of boar taint. Boar taint is the offensive odor or taste that can be evident during the cooking or eating of pork products derived from non-castrated male pigs once they reach puberty (Bonneau 1982). However, a small number of boars remain uncastrated and destined for breeding programs. Once these boars reach 6–9 months of age, they are moved to boar studs where they are trained to have semen collected from them. The animals learn to jump a phantom or dummy sow, and then in the presence of manual digital pressure from humans, the boars ejaculate and the semen is harvested. Boars are housed individually at boar studs to minimize inter-animal aggression, and semen is collected from them once or twice a week (Levis and Reicks 2005).

## Synonyms

Pig gait; Pig locomotion; Swine gait

## Definition

Movement used by swine (i.e., pigs) to traverse their environment.

Swine are even-toed, hoofed mammals that put weight on only two digits (i.e., artiodactyls). They belong to the genus *Sus* and are widely domesticated. Wild pigs for the most part live in forests or woodlands and are most active at night (Macdonald 2006). Wild swine forage in family parties and are omnivorous, feeding on a wide variety of plants, insects, and small vertebrates (Macdonald 2006). Wild pigs are mostly naked and only partly covered with thick bristles. They vary greatly in size, ranging from 58–66 cm and 6–9 kg in the pygmy hog to 130–210 cm and 130–275 kg in the giant forest hog (Macdonald 2006). Pigs are important animals for humans as they supply us with food resources, and we derive medicine from them. Therefore, understanding their locomotor behavior can benefit humans in relation to lameness and loss in productivity.

## Gait

Pigs walk with a four-beat gait sequence that alternates support phases between the involvement of two or three limbs (von Wachenfelt et al.

2008). These slower gaits are usually less than 1 km/hour and are observed during feeding, exploring, wallowing, and marking (Morelle et al. 2015). Under normal conditions these gaits are symmetrical. A symmetrical gait is when footfalls of the forelimb and hindlimb are evenly spaced in time. Symmetrical gaits can be further divided into a lateral sequence or a diagonal sequence. A lateral sequence gait is when each hindlimb footfall is followed by an ipsilateral forelimb footfall. A diagonal sequence gait is when each hindlimb footfall is followed by a contralateral forelimb footfall (Granatosky 2018). During walking gaits, forelimbs often travel together as slightly asynchronous pairs, forming couplets. Couplets are either lateral couplets, which means ipsilateral forelimbs and hindlimbs travel together, or diagonal couplets, which means contralateral forelimbs and hindlimbs travel together (Granatosky 2018; Hildebrand 1976; Hildebrand 1989). Walking gaits can be described as having a duty factor over 50%. A duty factor represents the time of the total cycle a given foot is on the ground. Stance phase occurs when the foot is in contact with ground and the limb is bearing weight. When the foot is not in contact with the ground and is moving in the air, the limb is in swing phase (Granatosky 2018). Wild pig species use lateral sequence lateral couplet and/or lateral sequence diagonal couplet footfall sequences (Fig. 1), but von Wachenfelt et al. (2008) reported a large proportion of diagonal sequence diagonal couplet gaits in domestic animals.

A pig's gait can differ based on the surface it is walking on (von Wachenfelt et al. 2008). When walking on greasy floors, pigs switch from a diagonal sequence gait to a lateral sequence gait. They do this by reducing their speed and progression length and prolonging their stance phase (von Wachenfelt et al. 2008). Different floor conditions have also been shown to alter braking and propulsion in pigs. The beginning part of the stance phase is usually involved in braking, and the end portion is usually involved in propulsion. In normal conditions, pigs tend to use their forelimbs for braking and hindlimbs for propulsion. However, when the floors are slippery, they tend to involve

**Swine Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in swine ( $n = 3$ )

more of their hindlimb for braking as well as propulsion (von Wachenfelt et al. 2008).

Swine did not evolve to run efficiently. In wild pigs, trotting is used to transverse long distances, and galloping is used for short bursts during emergency situations (Signoret et al. 1975). These fast-moving gaits can be defined as having a duty factor of under 50% (Granatosky 2018). Trotting is mostly reserved for social interaction by juvenile pigs and for movement between habitats. Trotting speeds for wild boars can vary between 6 and 10 km/hour (Morelle et al. 2015). A trot can be defined as the diagonal forelimb and hindlimb moving in unison. At high trotting speeds, there is suspension phase. This is when the diagonal couplet is in swing phase and the contralateral diagonal couplet has not yet touched the ground (Granatosky 2018).

At the highest speeds, wild boar and other swine use a transverse gallop (Jansen et al. 2009). Galloping mammals undulate their spines to increase the duration of swing phase and the stride length (Stavarakakis 2014). However, swine have not developed elongated limbs, making it difficult to keep a fast pace for more than a few minutes. This may be due to selection pressure for predator response because short-legged boars are

able to defend themselves without needing to run away (Morelle et al. 2015). Although other ungulates with longer limbs (e.g., deers) can maintain their top speeds for longer durations, swine have adapted by increasing their step frequency to compensate for short stride length (Clifford 2010). When boars need to flee from predators, they can reach speeds of 10–40 km/h (Morelle et al. 2015).

## Kinetics and Kinematics

Studying the kinetics and kinematics of animals can provide quantitative measurements of abnormal gaits and can subsequently help researchers identify aspects of lameness and injury in animal subjects. Thorup et al. (2007) offered an in-depth analysis of pig locomotor biomechanics. In terms of kinetic parameters, the study found that ground reaction force magnitude during normal gait are greater in the forelimbs. This finding indicates that a pig’s center of gravity is closer to the shoulder than it is to the hindlimbs (Thorup et al. 2008). Even though the forelimbs exhibit more force during locomotion, they are shorter and lighter than the hindlimbs. For this reason, the forelimbs present a site of common injury in pigs, including osteochondrosis and other joint pathologies (Thorup et al. 2007).

Studies of limb loading and biomechanical forces in pigs have also been used to analyze the chondral modeling theory, which revolves around joint development and cartilage growth in growing animals. The theory is defined as the adaptive growth response of cartilage in response to increased biomechanical forces on an animal; as the forces increase, changes in bone growth, cartilage thickness, and cellular division will occur to compensate and maintain stability inside a joint (Hammond et al. 2010). These studies have provided valuable insight into joint plasticity and remodeling.

The pig knee has been used as a model for understanding human joint injury. However, pigs have a greater range of flexion and a lower range of extension because of extension-restricted cruciate ligaments. The collateral ligaments in the pig

hold the joint in the craniocaudal axis and prevent abduction or adduction. They can also restrict rotation of the femorotibial joint along with the cruciate ligaments. Any alterations to the joint or to these ligaments can alter walking ability (Spitzers 2013).

### Gait in Young Swine

At birth young pigs gain locomotor function within their first couple of hours. The animal undergoes postural changes quickly that help it with walking. Vanden Hole et al. (2017) demonstrated that locomotion characteristics in young pigs (0–96 h) reach stable gaits within 4 h of birth, with most of them showing little change after the age of 2 h. These results indicate that coordinated movement patterns are not entirely innate, but that a rapid neuromotor maturation, potentially also the result of the rearrangement or recombination of existing motor modules, takes place in these precocial animals.

Pigs give birth to multiple offspring at once. This can lead to intrauterine crowding and affect birth size. Birth size can then affect stride length and stride frequency, thus affecting speed. The stride length in particular is affected by limb size of the animal. The more crowded the uterus is with offspring, the more competition there is for resources and the less the fetal pigs will develop. Piglets in general start out with low energy stores due to lack of brown fat. They get most of their energy from limited glycogen stores in their muscles and liver. The pigs cannot generate their brown fat until they start to consume fatty acids through milk intake from their mother. Due to the large number of offspring, this can then lead to competition among the newborns for milk and boxing out of undersized piglets. This leads to inadequate energy stores and diminished locomotor energy and muscle development. The consequences could result in altered gait (Vanden Hole et al. 2018a). An example of how intrauterine competition affects musculature has been observed in a reduction in *m. semimembranosus* cross-sectional area and myofiber count. This reduced cross-sectional area causes a diminished

ability to generate force and prevent gravity load collapse at joints.

### Swimming

Swine have been known to swim in search of food or to escape danger. In 2005, wild pigs in Texas were seen swimming to higher ground during intense rainfall and flooding. In fact, an island in the Bahamas has become famous for pigs swimming out to boats for food (Abernethy 2016). Some evidence suggests that swimming is an innate feature of pigs, and their ability to swim is aided by lung size and fat content under their skin (Gabbatiss 2017).

### Lameness

Lameness is an issue for farmers all over the world and is defined by a change from normal to impaired gait (Stavarakakis 2014). It can adversely affect the growth and reproductive potential of animals, leading to decreased farm productivity and profitability. Supakorn et al. (2018) reported that economic loss due to lameness in the USA was over \$23 million per year. Lameness often arises from lesions to pig hooves, which are commonly seen because of different floor types. Floors that are too abrasive can wear down claws and create lesions on the skin. Floors without enough abrasion can lead to excessive hoof growth (von Wachenfelt et al. 2008). Musculoskeletal and nervous system disorders can also lead to lameness (Stavarakakis 2014).

Osteochondritic lesions, for example, occur with damage to pig joints and are most common at the elbows and at the hip joint. These joints have the highest net movement in pigs which could help explain why they have the highest rate of cartilage damage (Stavarakakis 2014).

### Conclusion

The domestication of swine has allowed for extensive research about their locomotor

abilities. Domesticated and wild swine have several modes of locomotion that include walking, trotting, galloping, and swimming (Abernethy 2016; Signoret et al. 1975). Studies have shown that locomotion is almost innate to newborn pigs as they are able to walk within the first few hours of life (Vanden Hole et al. 2017). Due to domestication, pigs are bred to produce more offspring than normal. This has led to increased intrauterine competition and sometimes smaller piglets, which can affect gait, strength, and survival (Vanden Hole et al. 2018b). The gait of farm animals is very important in the agricultural industry. Lameness can reduce the productivity and profitability of farms, which can negatively affect the world's food supply. Understanding the locomotion of swine can help identify lameness and prevent it before it becomes a chronic problem. Also, identifying and altering poor swine living conditions that cause lameness can lead to positive economic results (Stavrakakis 2014).

## Swine Navigation

Joy Vincent  
Oakland University, Rochester, MI, USA

## Synonyms

Suidae navigation

## Definition

Members of the suidae family, commonly known as swine, are known for their flattened snouts and stocky builds, along with their demonstration of a number of cognitive abilities. Navigation is the capacity to orient oneself and purposefully travel through their environment to a destination.

## Introduction

The ability to navigate one's own environment is the result of the combined input of both internal and external cues (Morelle et al. 2014). Spatial cognition builds on this capacity, allowing individuals to use navigational cues to successfully travel through their environment. The suidae order consists of such species as the common warthog (*Phacochoerus africanus*), the wild boar (*Sus scrofa*), river hogs (*Potamochoerus porcus*), and domestic pigs (*Sus scrofa domesticus*). In general, swine tend to live in highly variable environments, necessitating the ability to navigate effectively through and remember key elements of their environment (Elmore et al. 2012). Swine rely on spatial memory to relocate important regions in their home

range, such as nests, burrows, waterholes, and lucrative food patches (Mendl et al. 1997). A plurality of swine species are considered to be highly adaptive, taking full advantage of the resources available to them in their environment (Treydte et al. 2006).

## Warthogs

Home ranges of warthogs overlap with other sounders; however, home sites are exclusive to individual family groups (Somers et al. 1994). Home ranges of different sounders tend to overlap more when they have stronger social ties (Podgorski et al. 2014). The ranges of warthogs vary among individuals and between regions. The average home range in Zimbabwe is  $167.13 \pm 91.53$  ha, whereas in Kenya it has been measured at 130 ha. In South Africa, matriarchal sounders were measured to have home ranges of  $26 \pm 11.34$  ha and bachelor herd ranges, which overlapped significantly with those of females, were measured at  $22 \pm 4.06$  ha (Somers et al. 1994).

Despite the variety in home range size, warthogs across the board showed a tendency to spend disproportionate amounts of time in specific regions of their home ranges. Within these regions, there is often a waterhole that the sounder preferentially visits (Somers et al. 1994). In Namibia, water distribution was a central facet of warthog movement throughout their home ranges (Somers et al. 1994). There is also an observable association between food availability and warthog abundance. One study found that, even more specifically, warthogs had the highest levels of activity throughout a day in regions with highly palatable grasses, demonstrating a preference for specific food resources (Treydte et al. 2006).

Females tend to disperse less than their male counterparts, resulting in increased levels of relatedness of females in close proximity to one another. It may be adaptive for females to remain within their natal territory, as they are able to benefit from their increased knowledge of bountiful food sources and reliable waterways

(Podgorski et al. 2014). Proximity to resources is particularly crucial for females, particularly those that are new mothers. Matriarchal sounders travel an average of  $1690 \pm 347.5$  m/day to forage. In contrast, a new mother was observed traveling only 638 m over the course of 5 days following the birth of her offspring (Somers et al. 1994). This is likely because of the reliance of her babies on her for nutrients and protection. In contrast, males tend to have home ranges that are larger than their female counterparts, covering the ranges of multiple female sounders (Somers et al. 1994).

Females with juveniles are the most particular about their choice in burrows, as they provide important refuge from the elements and predators (White and Cameron 2009). Unlike many other species on the African Savannah, warthogs rely less on their speed and stamina, and more on the utility of burrows as effective means to protect against predators. The burrows they inhabit are commonly repurposed from other burrowing species, such as aardvarks (White and Cameron 2009). They are commonly observed returning reliably to the same burrow over many nights, suggesting that they may exhibit high levels of fidelity to particular locations (Somers et al. 1994). In a survey of burrows, researchers found that, on average, only 25.1–59.6% of burrows are occupied at a given time. This relatively low occupation level may be due, in part, to predation and the chances of detection. In areas with higher occupation rates, predators may increase their presence as their chances of success are higher than in areas with lower densities (White and Cameron 2009). This is likely a prominent element in the selection of home sites within warthogs' home ranges.

## Wild Boar

Spatial memory in wild boar is highly dependent on individual experiences. On average, they are actively moving around their environment or foraging 40–65% of their days (Morelle et al. 2014). Their spatial distribution is strongly related to the resources available within an individual's habitat.

The space used by wild boars has a tendency to decrease as the available resources increase (Keuling et al. 2007). Conversely, when high population density is coupled with low resource availability, the distance traveled per day greatly increases (Morelle et al. 2014). These changes in resources are associated with seasonal changes, as different weather conditions affect the availability of resources. In the early summer, wild boars tend to increase their diurnal activity, often feeding in large open fields of cereals, as compared to forests and other habitats (Keuling et al. 2008).

Wild boars exhibit unique distribution patterns as functions of age and sex. Yearlings and adolescents tended to have larger shifts in their annual home ranges than adults and family groups. Yearlings had an average home range of 1,185 ha, ranging from 2,354 ha in the spring to 1,766 ha in the summer. This compares to family groups who had an average range of 771 ha, expanding to 791 ha in the spring and shrinking to 461 ha in the summer (Keuling et al. 2007). Females tended to show high fidelity to their native home ranges and exhibiting less seasonal variation in their annual ranges (Morelle et al. 2014).

### Wild Pigs

There are a number of attributes that contribute to the range and movement patterns of pigs, including age, sex, climate, and weather (Kay et al. 2017). Adult males have been observed to inhabit the largest home ranges when compared to females and juveniles (Kay et al. 2017). Wild pigs have immense home ranges, reaching up to 10,343 m<sup>2</sup>, with comparably smaller central regions, up to 964 m<sup>2</sup>, that they inhabit most often. A study found that they moved an average of 4,340 m in a 12-h period (Thomas et al. 2013). Although there was no significant difference, there was a tendency for the pigs to travel more at night (4,511 m) than during the daytime (4,169 m) (Thomas et al. 2013).

Individuals that lived near an abundant resource moved less throughout the day than their counterparts that did not have the same

access to food, suggesting that the main motivation for traveling during the day was motivated by searching for food in their environment (Kay et al. 2017). There is also a noticeable shift in home ranges during the summer months toward agricultural areas, which provide ample sources of food. Moreover, it is believed that wild pigs in drier climates move more than those in other climates because of differences in water resources; those in more humid climates have to cover less ground to find water sources (Kay et al. 2017).

### Red River Hogs

While red river hogs are found in a variety of habitats throughout their species distribution, they are limited by certain necessities. They require thick vegetation, water, and loose soil. They are often observed foraging along roadways, where there is ample vegetation on which to feed (Leslie and Huffman 2015). There have been reports of red river hogs traversing great distances as a result of speckled distribution of fruits within their ranges (Leslie and Huffman 2015). Sounders of red river hogs travel in single file lines, with their heads down and seem to rely most heavily upon their sense of smell for navigating their environment. They are easily approached from downwind, supporting the notion that they attend almost solely to olfactory cues ahead of them (Leslie and Huffman 2015).

### Peccaries and Wild Hogs

While the two species inhabit different niches in their environment, demonstrating different preferences for both habitat and food source, the distribution of peccaries is highly dependent on the movements of wild hogs (Isle and Hellgren 1995). A predictable pattern has been observed that when a herd of wild hogs moved into an area inhabited by peccaries, the peccaries would move to another area, avoiding overlap with the wild hogs. Peccaries are known to be highly territorial; this has been suggested as one explanation for the

distributions of these two species in the same region (Isle and Hellgren 1995).

## Optimal Foraging Theory

The optimal foraging theory suggests that animals should maximize their energy input (Gustafsson et al. 1999). Several theoretical models focus on specific conditions, and the behaviors that would maximize the effectiveness of an animal's foraging. The marginal value theorem (Charnov 1976) suggests that, as the cost of moving between food sources increases, the amount of time spent at specific patches should also increase (Gustafsson et al. 1999). In other words, the energy expended in moving between food patches should be made up for and exceeded by the amount of energy gained from foraging at a patch.

## Sensory Cues

Pigs have demonstrated their ability to forage and navigate through their environment using a variety of external and internal cues. It was long believed that pigs were ineffectual at using visual cues when foraging. However, more recent studies have contradicted these claims by showing their ability to use both visual and olfactory cues, either individually or in concert with one another (Croney et al. 2003). Pigs have also demonstrated the ability to associate outcomes with specific visual and olfactory cues in their environment, lending to the idea that pigs have the ability to use these cues when navigating their environment (Croney et al. 2003).

Despite their ability to make use of visual cues when foraging, pigs have historically performed better on tasks when relying on olfactory cues rather than visual ones. Pigs are known for their impressive senses of smell, which may help compensate for their relatively poor sense of sight (Croney et al. 2003). Wild boars are highly dependent on their sense of smell, relying on olfaction in various aspects of their lives, including antipredatory vigilance, socialization with conspecifics, foraging, and general

navigation throughout their territory. It is believed that moist air further enhances these abilities, which is further supported by their tendencies to be more active during periods of high humidity (Morelle et al. 2014).

Wild boars are able to use the information garnered from scents in concert with landmark cues to navigate their environments. They tend to remain in locations that are familiar to them, relying on previously established memories of specific landmarks (Cervený et al. 2016). This may allow them to formulate mental images or maps of their environment, which they use to relocate desirable locations for resting, along with places bountiful in food and water (Mendl et al. 1997; Morelle et al. 2014). Wild boars and other swine that normally frequent familiar environments may use a navigational strategy known as dead reckoning. This strategy is founded on certain assumptions, such as the animal's ability to remember various locations along with the distances and directions between such locations (Morelle et al. 2014).

There are a number of external and internal cues upon which swine may rely in their use of dead reckoning. Externally, they may rely on proximate cues, such as landmarks, or global cues, such as the stars, to orient themselves within their environment (Morelle et al. 2014). They may also use magnetic alignment (MA), which is the tendency for an individual to align themselves along geomagnetic lines. This tendency is often most pronounced during periods of calm, such as resting and foraging; species with pronounced magneto-receptor capabilities will orient themselves in predictable directions during these times (Cervený et al. 2016). MA allows for navigation that is free from changes in the environment, making it particularly useful for long-distance navigation or over the changing seasons (Cervený et al. 2016).

Both wild boars and warthogs have well-documented MA. Wild boars have a strong North-South preference aligning themselves along  $20^\circ/200^\circ \pm 3^\circ$  during bouts of foraging, showing a similar preference for the orientation of their nests. Warthogs demonstrate an almost identical preference of  $19^\circ/119^\circ$  while foraging

(Cervený et al. 2016). In both species, their MA tendency was stronger in juveniles and among larger groups of individuals; however, only in wild boars was it also more evident in males (Cervený et al. 2016).

## Disturbance Effects

Spatial memory in various species of swine is subject to interference from both internal and external forces (Mendl et al. 1997). Wild pigs are subject to a variety of meteorological disturbances that impact them in predictable ways. When exposed to extreme heat or extreme cold, wild pig movement decreased significantly (Kay et al. 2017). Movement was also impacted by air pressure, with the optimal range falling between 97,500 and 101,250 pa (Kay et al. 2017). There appears to be a relationship between air pressure and overall home range size; however, this may also be attributable to seasonal variations in home range coupled with reliable pressure changes across the seasons (Kay et al. 2017).

There have also been a number of disturbance effects that have been observed in the natural environments of wild boar and wild pigs. Notably, an investigation into the impact that hunting season has on the distribution of wild boar yielded a number of notable results (Keuling et al. 2008). Researchers found that following a single hunt, the distance at which an individual ran away in response to some oncoming stimulus – also known as their flight distance – for individuals in the area were significantly higher (Keuling et al. 2008). Additionally, the home ranges of individuals changed in response to the type of hunt they had experienced. Home ranges were larger for those that experienced a mixture of hunting methods, whereas those that lived in densely vegetated regions and experienced only a single hunt had far smaller ranges than would have been expected of individuals that were not impacted by hunting (Keuling et al. 2008).

A number of studies with domestic pigs in controlled arenas have provided additional insight into a variety of disturbances and their effects on domestic pigs' spatial memory. One of the most

overt instances of interference is the introduction of a novel environment. During inter-trial periods, when pigs were allowed to explore a novel environment, they performed significantly worse on the relocation trial than those that were not exposed to the novelty (Laughlin et al. 1999). Similar to exposure to a novel environment, the introduction of unfamiliar conspecifics has a comparable effect. The inverse – complete social isolation – also had detrimental effects on performance in spatial memory tasks (Laughlin et al. 1999). These patterns may be attributable to the increased stress levels associated with isolation or novel exposure; stress appears to have an adverse impact on spatial memory capabilities in pigs (Croney et al. 2003).

The impact of disturbances on pigs' performance in different spatial tasks appears to be dependent on the timing and ordering of the disturbances. When introduced sequentially during earlier trials, disturbances were highly impactful; however, over time, the introduction of novel stimuli had diminishing effects on their performance, suggesting that individuals were able to rapidly habituate to the disturbances (Laughlin et al. 1999). It may also be the case that longer intertrial periods could have adverse effects on pigs' performance levels. It has been hypothesized that a prolonged time delay may function as a reset on a pig's memory, rendering the relocation trial comparable to a novel search task (Mendl et al. 1997).

## Spatial Memory

Various swine species have demonstrated a reliance on memory, rather than proximate cues from the food reward during such spatial memory tasks (Morelle et al. 2014). Pigs systematically avoided locations they had previously searched. Over subsequent trials, they found food in fewer attempts than would be expected by chance (Mendl et al. 1997). Not only are pigs able to use their spatial memory to systematically search for food, but they are able to effectively relocate multiple sources of food that they had previously found (Held et al. 2000, 2010; Mendl et al. 1997).

Even neonatal pigs have demonstrated an ability to locate food at progressively faster rates during a series of acquisition and reversal tests (Elmore et al. 2012). When examining the overall distance traveled, similar to the amount of time required to relocate a food source, so too did distance decrease over repeated exposure (Elmore et al. 2012).

Win-stay and win-shift are terms used to describe two contrasting navigational strategies. They are differentiated by how individuals behave on subsequent searching tasks. “Win” refers to their acquisition of food and “stay” and “shift” refer to whether they continue returning to the same location or if they change locations. Thus, win-stay is when the individual returns to the same location on subsequent trials, whereas win-shift is when the individual changes locations. Pigs demonstrated an aptitude for win-stay tasks, despite them fully depleting the food source on previous trials (Mendl et al. 1997). This is likely due to their exposure to a pattern of depleted food sources being replenished while in captivity.

Despite this seeming proclivity of pigs in lab settings to adopt a win-stay navigational strategy, when food sources are not immediately replenished, they were able to adapt to the new circumstances. The most common method was to investigate the location immediately adjacent to the previously baited location (Mendl et al. 1997). This “moving one over” strategy, however, accounted for only 41% of the movements from the initial location. This suggests that, while they used this tactic in a plurality of instances, they were not adhering to just a simple navigational rule in an effort to avoid repeated visits to a given location (Mendl et al. 1997).

## Foraging Motivation

Pigs spend the majority of their waking hours foraging in their environment. Behaviors associated with the foraging process, such as rooting and traversing their environment, appear to be closely linked to their satiety. Stereotypical foraging behaviors have been observed in

higher prevalence in food-restricted individuals than those fed normally (Day et al. 1995). On the other end of the spectrum, however, were individuals that were presented food *ad libitum* and without the need for associated foraging behaviors. These individuals, despite their satiety, continued to behave in manners comparable to food-restricted individuals, suggesting that the end goal of foraging is not simply acquiring food (Moser et al. 2019).

Researchers have suggested that there is a close relationship between foraging and exploratory behaviors. Not only have pigs demonstrated increased foraging drives in regions with specific substrates, but they also exhibited a preference for novel objects, visiting regions where such objects are presented more frequently than the control areas (Moser et al. 2019). Another study found that patterns of exploration tend to differ among individuals, with some preferring to explore on the small scale and increasing their range, while others will explore the entire arena before focusing their energies on particular regions (Morelle et al. 2014).

## Domestication Effects

Swine species that are either domesticated or live in captivity show an aptitude for navigation and enhanced spatial memory, albeit in different capacities than their wild counterparts (Mendl et al. 1997). There is an argument that the navigational abilities of some domestic species have deteriorated over the generations, as they face less environmental pressures to maintain their adaptive capacities. They lack the need to avoid predation, starvation, and dehydration, diminishing their need to navigate over increased distances through their environment (Gustafsson et al. 1999).

In a series of studies, there were no perceivable differences detected between domestic pigs and their wild counterparts; both demonstrated the tendency to decrease the time spent at gradually diminishing food sources. The only perceivable difference was that the domestic pig spent longer periods of time at each individual

food source than the feral pigs (Gustafsson et al. 1999). This was likely due to the domestic pig's experience with food being presented in only one location and consistently replenished when depleted. They were able to employ a more energy-efficient foraging pattern by fully depleting a food source, as compared to the feral pig that changed locations more frequently so as to avoid depletion of specific patches (Gustafsson et al. 1999).

## Social Foraging

Many swine species live in complex social groups with distinct hierarchies. This complexity is evident when foraging either in pairs or groups (Held et al. 2000). Each individual's position in the social hierarchy should be reflected in how they behave in the company of other group members of different ranking. Dominant individuals, when in the company of those more subordinate, are expected to exhibit a certain set of behaviors, in the same way that subordinate individuals should perform actions that subvert the more exploitative behaviors of their dominant counterpart (Held et al. 2000). These predictable behavior patterns are evident in both the natural- and lab-based settings.

As mentioned earlier, Optimal Foraging Theory dictates that individuals should maximize their energy input. This can be accomplished by decreasing the amount of energy they exert while locating a food source. One solution is a common tactic seen in dominant pigs, known as scrounging (Held et al. 2002). Producers are individuals that locate food sources, expending their own energy in doing so. Scroungers, on the other hand, exploit the work of the producers, by following them to a food source and displacing the producer (Held et al. 2000). Generally, dominant pigs are larger and better able to displace subordinate producers, thus monopolizing the food source. In some cases, however, there are not major physiological differences between dominant and subordinate individuals rendering the displacement ability of the dominant individuals negligible. In this case, group members will often

rotate between the roles of producer and scrounger (Held et al. 2002).

In order to better study this phenomenon, the informed forager paradigm was developed to systematically alter the social conditions under which pigs foraged (Held et al. 2000). In this paradigm, subordinate pigs were given information about the location of a food source. They were then paired with a dominant partner who was naïve to the location of food in the arena. By releasing the two into the foraging arena together, researchers were able to observe the manifestation of scrounging behaviors and the behaviors exhibited by the informed individual to this exploitation (Held et al. 2000). They found that both pigs exhibited predictable behaviors in line with their roles as producers or scroungers (Held et al. 2002).

When alone, dominant pigs behaved like producers, searching for their own food. However, when they were presented with an alternative, they changed their behaviors to follow their subordinate partner to a food source (Held et al. 2010). Six out of the eight dominant individuals tested in this manner displaced their subordinate partner when they arrived at a food source (Held et al. 2000). The most common response to this exploitative behavior was for the subordinate pig to increase their speed. This nondeceptive behavioral change would allow them to better capitalize on their advantage – of knowing where the food was located – by increasing the distance between them and their partner, thus increasing the time before displacement (Held et al. 2010).

In a follow-up study, researchers introduced a third type of foraging partner. This pig was dominant to the informed individual but was not competing for the food source, as this new partner learned that food was always located in a location separate from the locations learned by the subordinate, informed pig. When paired together, the behavior patterns observed previously, in response to an exploitative partner, were not present (Held et al. 2010). There was additional variation in the behavioral responses of subordinate individuals that were associated with the current behaviors of the dominant pigs. Subordinates showed a tendency to move away from the baited locations when there was a high likelihood of

interference by the dominant individual: when they were being followed closely, when they were being watched, and when the dominant was closer to the food source than the subordinate (Held et al. 2002). Conversely, when the dominant individual was moving away from the food source, out of sight of the subordinate, or the subordinate was closer to the food source than the dominant, the subordinate pig would often approach the baited location at a quick pace (Held et al. 2002).

There is a benefit for producers to maximize the distance between themselves and potential scroungers, and a converse benefit for scroungers to maintain minimal distances with numerous producers (Held et al. 2002). In the wild, it is common to find producers foraging on the periphery of the group, while the more dominant scroungers occupy the center of the group (Held et al. 2002). This pattern reflects the optimal positioning of different members of the group based on their foraging strategies.

## Conclusion

Across the various species of swine, there is a consensus that they have impressive navigation capabilities that are put to use in their individual environments. The ability to navigate effectively is necessitated by resource availability. Food, water, and shelter are crucial to an individual's survival, and a majority of their waking time is spent searching for these resources. While they are able to employ their visual systems in navigation, they commonly defer to their sense of smell, demonstrating heightened abilities to discriminate stimuli in their environment via olfaction. Warthogs and wild boars have demonstrated a proclivity for magnetic alignment, which may be used in concert with landmark orientation, allowing them to employ dead reckoning to navigate their environment. The sociality of swine species manifests in a variety of predictable behaviors patterns associated with each individual's position in the group hierarchy and the subsequent role they perform while foraging. There is still much to learn about the specific navigational

strategies employed by different swine species and how they may manifest in navigation through natural habitats.

## Introduction

Symbiotic relationship or symbiosis is a kind of close association between two organisms belonging to same or different species in nature which might benefit one or both organisms (Moran 2006). The word symbiosis is derived from Greek words sym meaning together and bios meaning life, translating into “different lives working together.” Symbiotic relationships may be obligate where both organisms cannot live independent of each other, for example, ants and the acacia plant, or facultative where the association is not compulsory for both to survive, for example, honeybees and flowers. Each organism in a symbiotic relationship is called symbiont. When one symbiont lives on the body surface of the other, it is called ectosymbiosis, for example, head lice on human scalp. In endosymbiosis one organism lives inside the body of the other, for example, nitrogen-fixing bacteria living inside the root nodules of leguminous plants (Sherwood et al. 2013).

Symbiotic relationships may be one of the three types: mutualistic, commensalistic, and parasitic. In a mutualistic relationship, both interacting organisms are benefitted from each other, for example, clownfish and sea anemone, lichens (algae or cyanobacteria and fungi), mycorrhiza (higher plants and fungi), etc. In a commensalistic relationship, one organism is benefitted off from the other, while the other one is neither harmed nor benefitted,

for example, cattle egrets and livestock, remora fish and sharks, orchids growing on trees, etc. In a parasitic relationship, one organism lives off on other organisms benefiting from it while harming the host or even causing death of the host organisms, for example, viruses living in their hosts, fleas or ticks that live on dogs and cats, etc.

A well-known example of endosymbiotic relationship is between the termite and microorganisms living in the digestive tract of the termite. The microorganisms like bacteria, archaea, and protozoans digest the complex sugar like cellulose in wood into simpler short-chain fatty acids like acetic acid that they can use for food. In a similar manner, human body is inhabited by numerous microorganisms which play key roles in different aspects of human health (Cani 2018). The Human Microbiome Project was aimed at sequencing the genome of the human microbiota, inhabiting the skin, mouth, nose, digestive tract, and vagina (Turnbaugh et al. 2007; Duffy et al. 2015). It is estimated that the number of bacterial cells is ten times the number of cells present in human body (Bull and Plummer 2014).

## Mutualism

Mutualistic relationships can be categorized into three classes:

1. **Resource-resource relationship:** In this kind of association, one resource is given in exchange for other resource. Classical example of such relationship is between nitrogen-fixing bacteria like rhizobium and leguminous plants like pulses and pea. Plants cannot use free atmospheric nitrogen; therefore, bacteria fix atmospheric nitrogen into nitrite and nitrate which can be easily absorbed by plants, and in return bacteria gets shelter and nutrients from root nodules of the plant.
2. **Service-resource relationship:** In this relationship, one organism pays the other in the form of resource in exchange for its services. Zoophily, i.e., pollination with the help of insects, is a classic example of service-resource mutualistic relationship where insects like bees and wasps pollinate the flowers and in return rewarded with nectar. The honey bee collects nectar in honey sac for its deposition in colonies for later use, and in the process pollens stick to their legs and body. When the same bee lands on another flower to collect nectar, the pollens are transferred to that flower resulting in pollination. The relationship between ants and aphids also comes under this kind of mutualistic relationship. Aphids are small plant sap-sucking insects which produce honeydew as a by-product which they trade in return of protection from predators like ladybug; ants also protect aphids from fungal diseases. Another example of such association can be seen between oxpecker birds and rhinoceros or impala. Oxpecker bird gains a safe habitat on rhinoceros's back and in return eats ectoparasites and insects that would harm rhinoceros providing cleaning services (Losey 1972; Poulin and Grutter 1996). Plants offer sweet fleshy berries to the birds as resource; the seeds of the fruit are then dispersed to different places where the birds fly leading to their vegetation at new places.
3. **Service-service relationship:** Both organisms in this kind of association provide service to each other. Classical example of such association is between clownfish (*Amphiprion clarkii*) and sea anemone (*Stichodactyla haddoni*). Sea anemone protects the clownfish against predators using stinging nematocyst which is ineffective against clownfish due to the presence of thick mucus layer. In return clownfish protects the anemone against butterflyfish which feeds upon the anemone. Another example of such association is between acacia and ants (*Pseudomyrmex ferruginea*) which live on the bullhorn acacia (*Vachellia cornigera*). The ants provide protection to the plant from grazing animals, and in return to this service, plants provide food and shelter to the ants.

## Commensalism

The word commensalism means “eating at the same table” or “sharing a table” and is derived

from Latin words *com* meaning together and *mensa* meaning table/meal. As described above, in commensalism, one organism is benefitted and is called the commensal which is generally smaller, while the host which is generally bigger is neither harmed nor benefitted. The commensal may gain protection, nutrition, shelter, or transportation (Hulme-Beaman et al. 2016).

Most common example of commensalism is seen between remora fish (family Echeneidae)/pilot fish and sharks or other big fishes. Remora fish attaches itself to the big fishes with the help of a sucking structure present on their heads and gains protection, travels to great distance without spending its energy to swim, as well as feeds on the leftover food from shark. Another example of commensalism is between bird species such as the great egret (*Ardea alba*) and grazing animals where birds feed on small insects that are turned up from soil and grass by grazing mammals. Various biting lice, fleas, and louse flies are commensals in that they feed harmlessly on the feathers of birds and on sloughed-off flakes of skin from mammals.

Another example of commensalism is that of the pseudoscorpion which are very small scorpions lacking any stings and larger flies. Pseudoscorpions stick to the legs of the flies and take a ride from one place to another without affecting the fly. Once the scorpion reaches its destination, it detaches from the fly and the association is ended. In a similar manner, large marine animals are often surrounded by a group of small fishes or other aquatic animals, for example, barnacles are associated with whales and other small fishes feed on the leftover food from sharks. In the same way, small bait fishes can often be seen in large schools under the large fins of the manta ray for protection from birds which otherwise dive and feed on them. At the same time, manta ray hardly notices the presence of bait fishes under it.

Another interesting example of commensalism can be seen in the bur (seed or dry fruit having hooks or teeth) of burdock plant. Often when passing through fields, several seeds having small spikes get attached to the lower sides of our cloths and travel from one place to another

getting dispersed to different places and start their vegetation at new habitats.

## Parasitism

Parasitism describes a relationship between two organisms where one benefits while the other is harmed. The parasite is the organism that benefits from the relationship, while the host is harmed by the relationship. Parasites can be plants, animals, viruses, or bacteria (Poulin 2011). Parasites are considered ecologically important as they can shape community structure through their effects on trophic interactions, food webs, competition, biodiversity, and even keystone species (Preston and Johnson 2010). Parasites may be ectoparasites living on the body surface of the host like ticks, fleas, leeches, and lice or endoparasites living inside the host body like bacteria, viruses, flukes, and parasitic protozoans. The word parasite is derived from Greek word *parasitos* meaning “one who eats at the table of another.” Parasites show variety of adaptations according to their hosts. Parasites can alter the physiology and behavior of the host, resulting in changes in growth rates, density, survival rates, life span, reproductive fitness, and competitiveness in order to maximize their growth, reproduction, and transmission (Thomas et al. 2011; Poulin 2010; Lefèvre and Thomas 2008).

Plant parasites are generally divided into two types, necrotrophic and biotrophic parasites. Necrotrophic parasites eat a part of host tissue until it dies, for example, *Botrytis cinerea* pathogen causing gray mold in tomato plant, while biotrophic parasites does not kill the host as it cannot survive without the living host, for example, *Blumeria (Erysiphe) graminis* causing powdery mildew in grasses or cereals. Epiphytes are the plant parasites that grow on the surface of other plants and obtain moisture and nutrients. Most common epiphyte is orchids (Westwood et al. 2010).

On the ability to complete their life cycle in one or two hosts, animal parasites are generally divided into monogenic parasites and digenetic parasites. Monogenetic parasites complete their life cycle in only one individual host, while

digenetic parasites need more than one host to complete their life cycle. *Plasmodium vivax*, causative agent of malaria, is a digenetic parasite as it requires both mosquito and human to complete its life cycle. *Entamoeba histolytica* is a monogenetic parasite as its life cycle is completed on one host only, human (Lefèvre and Thomas 2008).

In nature, sometimes parasites are found whose host is the parasite on other organism; such parasites are called epiparasites or hyperparasites or secondary parasites. Hyperparasitism is generally seen in Hymenoptera (wasps), Diptera (flies), and Coleoptera (beetles). Most common example of hyperparasitism can be seen in white butterfly (*Pieris rapae*) whose larvae are parasitized by the larvae of the wasps *Cotesia glomerata* and *C. rubecula*, which in turn is parasitized by the wasp *Lysibia nana* (Poelman et al. 2012; Yong 2012).

Some parasites require an organism other than their definitive host to transfer them from one host to another; such organism is called vector or carrier. Mosquitos (*Aedes*, *Culex*, and *Anopheles*), sandflies, ticks, fleas, lice, and tsetse flies act as vector for numerous disease-causing parasites which cause grave diseases like malaria, chikungunya, dengue fever, lyme disease, sleeping sickness, etc. (Garcia 1999; Esch and Petersen 2013). Vector-borne diseases account for more than 17% of all infectious diseases, causing more than 7 lakh deaths annually.

## Obligate Parasitism

The parasites which are completely dependent on their host for survival are called obligate parasites. Such parasites cannot thrive in absence of their host and soon dies. These parasites generally do not kill their host as a part of their survival strategy. One example of obligate parasitism is head lice in human, as they cannot survive once removed from scalp.

## Facultative Parasitism

The parasites that do not completely rely on host for the completion of their life cycle are called

facultative parasites. For example, nematode *Strongyloides stercoralis* infects human and cause strongyloidiasis disease, but it can also be found free-living.

## Brood Parasitism

It is most commonly seen in species of cowbirds and cuckoos which lay their eggs in the nest of other birds like reed warbler or Eastern phoebe and leave them to be raised by the host birds without investing any resources in it. Sometimes these birds also remove some of the eggs of the host bird.

## Symbolic Distance

Damian Scarf  
Department of Psychology, University of Otago,  
Dunedin, New Zealand

## Synonyms

Distance effect

## Definition

The time needed to compare symbols varies as a function of their distance.

The symbolic distance effect describes the fact that the “time needed to compare two symbols varies inversely with the distance between their referents on the judged dimension” (Moyer and Bayer 1976, p. 229). The effect was originally observed with psychophysical stimuli. For example, Johnson (1939) had participants throw one of two switches to indicate the longer of two lines. The lines differed in length by 1, 2, 3, 4, 6, 8, or 10 mm. He found that response time was an inverse function of the length difference between the two lines. That is, participants were faster to indicate the longer of two lines when their length difference was 8 mm compared to when it was 2 mm. Moyer and Landauer (1967) were the first to observe the effect with stimuli whose order was represented symbolically. They presented participants with pairs of numerals, drawn from the numerals 1 to 9, and instructed them to indicate the larger of the two. They found that as the numerical distance between the two numerals increased participants’ reaction time decreased. For example, participants’ reaction time was longer when the two numerals being compared were separated by a distance of one (e.g., 3 vs. 4), slightly shorter when the numerals were separated by a distance of two (e.g., 6 vs. 8), and so on, with reaction time the shortest when numerals were separated by the maximum distance of eight (i.e., 1 vs. 9). The effect has since been observed with a range of well-learned sequences, such as the alphabet (Hamilton and Sanford 1978; Jou and Aldridge 1999; Lovelace and Snodgrass 1971; Van Opstal et al. 2008), months of the year (Gevers et al. 2003), and days of the week (Gevers et al. 2004).

In nonhuman animals, the symbolic distance effect has primarily been investigated using the simultaneous chaining paradigm (Scarf and Colombo 2008; Terrace et al. 1977). Briefly, the paradigm involves presenting subjects with a list consisting of  $n$  number of simultaneously displayed items. The subject’s task is to respond to each item of the sequence in a prescribed order learnt during training. Similar to the studies of

**Symbolic Distance, Fig. 1** Symbolic distance effect for pairs beginning with item B and pairs beginning with item C for humans and monkeys

serial learning in humans, following training, each pair of items that can be derived from the list is presented to subjects. Much like the months of the year or the days of the week, the more distant two items are on a list, the more discriminable they should be in the sense that it should be easier to determine which of the two comes first. For example, on a five-item list ( $A > B > C > D > E$ ), the latency to respond to stimulus A should decrease across pairs AB, AC, AD, and AE; the latency to respond to stimulus B should decrease across pairs BC, BD, and BE; and the latency to stimulus C should decrease across pairs CD and CE. In reality, however, because item A occupies the first position of the list, and because responses to it are typically very quick, it is very hard to observe a symbolic distance effect for pairs with A as the first item. Taking this into account, as shown in Fig. 1, both humans and capuchin monkeys display the symbolic distance effect on the simultaneous chaining paradigm (Colombo and Frost 2001; D'Amato and Colombo 1990). Beyond these species, the effect is observed in a wide variety of animals including rhesus monkeys (Gazes et al. 2012), ring-tailed lemurs (MacLean et al. 2008), pigeons (Scarf et al. 2011), and corvids (Bond et al. 2010).

With respect to theories of serial learning, the symbolic distance effect accords well with the ordinal position hypothesis but not the remote association hypothesis (Potts 1972, 1974).

According to the remote association hypothesis, reaction time should increase as the distance between items increases. That is, because the associative strength between two items decreases with distance, reaction time is expected to increase as the distance between the members of the pair increases (Moyer and Bayer 1976; Terrace 2005). In contrast, the ordinal position hypothesis predicts that reaction time will decrease as a result of participants comparing the ordinal positions of the paired items (Jou and Aldridge 1999; Moyer and Bayer 1976). That is, when a pair is presented, a participant first identifies the ordinal positions of each item and then compares them in order to determine the earlier or later member of the pair.

## Summary

The symbolic distance effect has been observed in both humans and animals using a range of stimuli, from months of the year in humans (Gevers et al. 2003) to numerical stimuli in pigeons (Scarf et al. 2011). The fact the symbolic distance effect is observed across species suggests that humans and animals represent serial stimuli in a comparable manner.

## Synteny

Ignacio Maeso

Department of Gene Regulation and Morphogenesis, Andalusian Centre for Developmental Biology (CABD), CSIC/ University Pablo de Olavide, Seville, Spain

### Definition

From the Greek *συν* (*syn*), “together with,” and *ταινία* (*tainia*), “ribbon.” Physical linkage of two or more genetic loci on the same DNA molecule. Shared or conserved synteny refers to ancestral syntenic loci that have maintained their physical linkage in two or more descendant lineages (Irimia et al. 2013).

### Introduction

Any given genomic feature or locus (such as a gene, a promoter, an enhancer, etc.) can be located either in the same or in a different DNA molecule/ chromosome than another genomic element; that is, the two loci can either be syntenic or nonsyntenic. Certain syntenic associations are of particular biological relevance because of their functional consequences (as in syntenic genes that belong to the same operon or in linked genes sharing a common set of *cis*-regulatory elements) and can therefore be subjected to the action of natural selection. In many other situations, syntenic linkages between loci have no obvious phenotypic impact, in which case synteny can evolve neutrally.

### Types of Synteny

Synteny can be considered at two different genomic scales (Irimia et al. 2013):

- Microsynteny: fine-scale syntenic associations between immediately adjacent loci (i.e., gene

order), with no (or very few) intervening genes separating these loci.

- Macrosynteny: syntenic linkage at the chromosomal (i.e., “macroscopic”) level, regardless of the distance and number of intervening genes interspersed between the syntenic loci.

### Synteny Evolution and Its Relationship with Gene Regulation

During evolution, ancestral syntenic associations can be disrupted by chromosomal rearrangement mutations. Accordingly, different patterns of synteny conservation can be found across different groups of eukaryotes, depending on the frequencies of inter- versus intrachromosomal rearrangements in each lineage. Thus, a high prevalence of inversions (intrachromosomal) leads to degradation of large-scale microsynteny while keeping macrosyntenic associations, whereas high incidence of translocations (interchromosomal) degrades both microsynteny and macrosynteny. Regardless the case, for most genes, their order along chromosomes has few or no implications for organismal function and is generally thought to be largely random; as a result, the degree of synteny conservation between two lineages broadly correlates with the evolutionary rates and divergence times of these lineages. However, there are important exceptions to this general trend, and some pairs of genes can maintain their microsyntenic linkage over hundreds of millions of years of evolution (Engström et al. 2007; Kikuta et al. 2007; Simakov et al. 2013; Irimia et al. 2012). These associations indicate functional implications for gene order and appear to largely reflect *cis*-regulatory constraints preventing the disruption of microsynteny. These constraints are related to either (i) multiple genes sharing transcriptional regulatory elements, or (ii) genes with long-range *cis*-regulatory elements that can be located at very long distances, even intermingled with the introns of unrelated neighboring genes (Irimia et al. 2012). While (i) can be found throughout

eukaryotes, involving pairs of genes that are tightly coregulated by a shared bidirectional promoter, in the case of (ii), long-range regulatory elements have only been found in animals, where they regulate the complex expression patterns of genes involved in animal embryogenesis (Irimia et al. 2013).

## Conservation of Microsynteny and Allelic Association Studies

The presence of transcriptional regulatory elements that can be located far away from their target genes, as it is often the case in genes with important functions during animal development, can lead to misidentification of the causal genes in allelic association studies (such as Genome-Wide Association Studies (GWAS)). The identification of blocks of conserved microsynteny overlapping with the associated allele can help defining the genomic region where the gene responsible for the observed phenotype could be located, especially in cases where the causative gene is not the closest one to the sequence variant (Smemo et al. 2014).

## T.H. Huxley on Human and Ape Brains

Vincent Barnett

Independent Scholar, London, UK

### Definition

Thomas Henry Huxley (1825–1895) was Charles Darwin's most enthusiastic bulldog-advocate, a renowned Professor of Natural History in his own right, and the author of important works on evolution such as *Evidence as to Man's Place in Nature* (1863). One of his most significant published outputs was the section entitled "Note on the Resemblances and Differences in the Structure and the Development of the Brain in Man and Apes" that was included in the second edition of Darwin's *The Descent of Man and Selection in Relation to Sex*, and which will be a main focus of this entry.

### T.H. Huxley

Huxley was initially a medical practitioner before studying botany, eventually becoming Professor of Natural History at the Royal School of Mines. Important to his intellectual development was a period acting as the ship's surgeon on the HMS *Rattlesnake*, during which he worked (in part) on improving the animal classification system and on

embryology. Later he founded the scientific approach to craniology and developed a new system of bird classification (Abbott 1983, pp. 70–71).

Huxley has been accurately categorized as more of a comparative anatomist, a zoologist, and a physical anthropologist, rather than a conventional naturalist (Freeman 1978, p. 170), and also as a bold personality complement to Darwin's meticulous study. Darwin described Huxley as follows: "He has been a most kind friend to me and would always take any trouble for me. He has been the mainstay in England of the principle of the gradual evolution of organic beings. Much splendid work ... he has done in Zoology" (Barlow 2005 [1958], p. 88). As an example, Huxley provided an original evolutionary genealogy of the horse (from *Eohippus* to *Equus*) that quickly became a "paradigm fossil proof for evolution" (Desmond 2002, p. 551; Huxley 1877), and he also provided an influential analysis of evolutionary ethics (Huxley 1893).

Huxley became well-known in the UK in relation to the debates around the publication of Darwin's *The Origin of Species* in 1859 and thereafter as a staunch defender of the idea of the evolution of animal and plant life by means of selection mechanisms. His famous response to first learning of the idea of natural selection was: "How extremely stupid of me not to have thought of that!" (Freeman 1978, p. 170). Huxley had corresponded with Darwin from the early 1850s onwards on various natural history topics and first visited him at Down House in 1856.

Huxley quickly published very positive reviews of *The Origin of Species* in *The Times* and in *Macmillan's Magazine* and lectured on it in 1859 and 1860, counting as one of Darwin's most loyal supporters (Nocks 2008, pp. 60–61). Although Huxley initially expressed some doubts about particular aspects of Darwin's theory, he never from 1859 onwards doubted the reality of evolution in the general sense. Indeed, he had delivered a lecture on "the progressive development of animal life" even before the *Origin* was published (Huxley 1855), and he was still defending Darwin's work in print over a decade after the publication of the *Origin* (Huxley 1871). When Darwin died, Huxley was a Pall Bearer at his funeral and wrote an obituary that compared him to Socrates for his belief in the absolute sovereignty of reason (Huxley 1999 [1882], p. 396).

### ***Evidence as to Man's Place in Nature***

Published 4 years after the first edition of Darwin's *The Origin of Species*, Huxley's most well-known book-length work *Evidence as to Man's Place in Nature* began (unusually for a work of natural history) with a substantial historical account of the treatment of what he called the "man-like apes" (or catarrhine apes) in previous works of natural history, starting as early as 1598. It then provided a detailed comparative analysis of the physical structure of human beings (what he called their "animal fabric") and their embryonic development compared to "the lower animals," and it finished with an account of various fossil remains of archaic human beings such as the Neanderthal skull that had been discovered in 1856. Huxley erroneously concluded that the Neanderthals were not a distinct or intermediate form between human beings and their primate ancestors (Huxley 1863, p. 183), in line with the accepted doctrine of the period. Now it is known that Neanderthals are a separate species from modern humans (Lieberman 2013, p. 105). Elsewhere, Huxley mapped the geographical distribution of what he called "the chief modifications of mankind" (Huxley 1870a).

*Evidence as to Man's Place in Nature* also included as a frontispiece a much-reproduced

illustration comparing the skeletons of (from left to right) the gibbon, the orang-utan, the chimpanzee, the gorilla, and then "man" in a way that suggested an evolutionary progression that has been described as the "most well known, but misunderstood piece of artwork in the history of evolution studies," in part because the evolutionary sequence that was implied in it is not accurate (Nocks 2008, p. 58). Human beings are more closely related to chimpanzees and bonobos than to gorillas. Some significant time later, a book with the title *History of the Primates* would present a more accurate cover illustration of the progression of primate evolution (Clark 1962), while Ernst Haeckel had published a more extensive evolutionary tree of life in 1902 that contained four major groups of phyla.

Overall, the argument was clearly made throughout *Evidence as to Man's Place in Nature* with a wealth of supporting evidence that human beings were very close in structural terms to their closest primate relatives, exactly as Darwin's 1859 theory of evolution had implied. For example, on embryonic development, Huxley concluded that:

Without question, the mode of origin and the early stages of the development of man are identical with those of the animals immediately below him in the scale: - without a doubt, he is far nearer the Apes, than the Apes are to the Dog (Huxley 1863, p. 81).

On cranial capacity, Huxley outlined that human beings differed more widely from one another than they did from some of the apes, the lowest apes differed as much in cranial capacity from the highest apes as the latter did from human beings, and males brains were (on average) somewhat larger than female brains. Huxley also provided an in-text illustration comparing a human skull with five other types of ape skull that diverged from the former in varying degrees (Huxley 1863, pp. 96, 94).

In general, whatever part of the animal fabric was considered, Huxley maintained that the lower apes and the gorilla differed more than the gorilla and human beings (Huxley 1863, pp. 95, 101). Although *Evidence as to Man's Place in Nature* was only concerned with physical comparisons between human beings and their closest primate

relatives, elsewhere Huxley maintained that “the same nervous structures underlay cognitive processes in man and the higher animals” (Richards 1987, 228). He concluded the book by suggesting that, because of the consequences of the theory of evolution, “we must extend by long epochs the most liberal estimate that has yet been made of the antiquity of Man” (Huxley 1863, p. 184).

Having provided this free-standing account of the issue of comparative morphological development, Darwin duly selected Huxley to provide a tailored short summary of his approach on this topic for one of his most significant works, *The Descent of Man*, chapter one of which on the evidence of the descent of man from a lower animal form was very similar in both general aim and specific content to Huxley’s own *Evidence as to Man’s Place in Nature*.

### On Human and Ape Brains in *The Descent of Man*

In the Preface to the Second Edition of *The Descent of Man* of 1874, Darwin wrote: “I must especially call attention to some observations which I owe to the kindness of Prof. Huxley (given as a supplement at the end of Part I), on the nature of the differences between the brains of man and the higher apes” (Darwin 1874 [1871], v). This addition by another author was the only such addition included by Darwin in his most significant books. Huxley’s wider importance to *The Descent of Man* is indicated by the fact that he has (in the second edition) 17 separate page references listed in the book’s rear index, only one of which was to the “Note on the Resemblances and Differences in the Structure and the Development of the Brain in Man and Apes.”

In the first edition of *The Descent of Man* of 1871, Darwin had briefly discussed Huxley’s work on comparative anatomy as showing that the brain of “man is constructed on the same general type or model with other mammals” (Darwin 1881 [1871], p. 10), as against critics such as Theodor Bischoff who had emphasized developmental differences. For the second edition of *The Descent of Man*, Darwin asked Huxley to

fill in the gap about comparative brain anatomy with a section devoted to presenting the latest knowledge on the topic, in order to bolster his own case for the evolutionary connections between “man” and the higher apes (Browne 2003, 343), which he then added to the end of the first major part of the book.

As Huxley explained in the provided section (of eight printed pages), it was Louis Gratiolet who had originated the statement that there was a fundamental difference in the developmental growth of the brains of apes and those of human beings (Huxley 1874, p. 203). This was part of the wider argument that the brains of apes differed significantly from those of humans, for example, in the posterior lobes of the cerebral hemispheres. In contrast, Huxley maintained that (for example) the sulci and gyri (valleys and folds) that appeared on the surface of the cerebral hemispheres “are disposed after the very same pattern” in human beings and in the higher apes (Huxley 1874, p. 199). In his earlier *Evidence as to Man’s Place in Nature*, Huxley had included detailed illustrations of a human brain next to a chimpanzee’s brain and had concluded using this visual comparison that the structural differences which separated human beings from the gorilla and the chimpanzee were not as great as those that separated the gorilla from the lower apes (Huxley 1863, p. 123). One of Darwin’s basic conclusions from *The Descent of Man* echoed this Huxley point almost exactly (Darwin 1874 [1871], p. 150).

Huxley readily admitted in his “Note on the Resemblances” that there were some accepted differences between human and ape brains; for example, the cerebral hemispheres of human beings were larger than those of the orang-utan and the chimpanzee and the gyri and sulci had a greater number of secondary corrugations, but “none of these differences constitute a sharp demarcation” enough to suggest that they are of a fundamentally different type or are evolved from a different origin (Huxley 1874, p. 200).

In addition, Huxley pointed out that some brain structures varied within the limits of a single animal group, such as between the Old World apes and the New World apes, which had differences in

their temporo-occipital sulci, so the fact that such structures might also differ in human beings to a degree had no great taxonomic value. Huxley concluded his comparative account of the brain in “man” and apes with a section on embryology and with the sentiment that the exhibited growth of the fetal human brain is in perfect harmony with the general concept of evolutionary development.

### The Evolutionary Significance of *Archaeopteryx*

Huxley’s skills in comparative anatomy were not limited only to analyzing brain structures. For example, he was the first commentator to use what he called “comparative zoological reasoning” in order to explicitly highlight the intermediate nature of the skeletal form of *Archaeopteryx lithographica* (Huxley 1863, p. 85), which was from the late Jurassic period. Huxley called the *Archaeopteryx* fossil a connecting form and he listed 35 different morphological characteristics in order to substantiate his connecting claim (Huxley 1868, p. 358; Currie and Padian 1997, p. 809).

Although the *Archaeopteryx* fossil had been first discussed in print by Huxley’s nemesis as an anatomist Richard Owen (1863), Owen had missed the intermediate nature of the bodily structure that was on display in part due to his general skepticism about the theory of evolution, and he had also (in haste) erroneously mislabeled some parts of the *Archaeopteryx* skeletal anatomy. More accurately, Huxley compared *Compsognathus longipes*, a chicken-sized bipedal meat-eating theropod (another bird-like dinosaur), to *Archaeopteryx* as a dinosaur-bird intermediary, the two animals having some definite structural similarities/evolutionary homologies (Herbert and Norman 2009, p. 151). Although the first *Archaeopteryx* fossil lacked a skull, Huxley predicted that if one was found, it would have teeth like a reptile, not a toothless bill like a bird: Owen took the latter view. It was Huxley’s predication that turned out to be correct (Lindow 2008, p. 369).

Huxley’s original theropod hypothesis for the origin of birds is now accepted as the correct

approach to understanding avian evolution even though during the second and third quarters of the twentieth century, it was supplanted by a different erroneous theory due to some remaining anatomical doubts (Padian and Chiappe 1997, pp. 72–73). Huxley’s theropod hypothesis – birds as flying dinosaurs – was resuscitated and further confirmed in the 1970s (Ostrom 1974), and he also proposed in terminology that dinosaurs should be classified as the *Ornithoscelida* (Desmond 2002, p. 551). On a second paper on connecting forms, Huxley had further analyzed the anatomical similarities between birds and dinosaurs, conceiving the *Megalosaurus* (another theropod dinosaur) as Ostrich-like in some significant ways (Huxley 1870b).

Even though Huxley’s *Archaeopteryx* work was an important contribution to comparative anatomy in its own right, its crucial significance for the theory of evolution was cemented by the fact that this fossil was the first clear example of a so-called missing link or transitionary form of animal that was discovered in the fossil record, and Darwin was subsequently able to incorporate this fact in the fourth edition of *The Origin of Species* of 1866 as further proof of the validity of his approach. The original *Archaeopteryx* fossil quickly became one of the “crown jewels” of palaeontology discovery both because of its evolutionary significance and due to the extremely fortuitous timing of its first discovery, although various other examples of it have subsequently been found.

Utilizing the existing work on the *Archaeopteryx*, Darwin suggested in *The Descent of Man* (following Huxley’s lead from his 1870b article) that this fossil provided direct evidence that “the Dinosaurians are in many important characters intermediate between certain reptiles and certain birds” (Darwin 1874 [1871], p. 158). As has been suggested, “*Archaeopteryx*, more than anything else, helped vindicate Darwin’s theory” (Lindow 2008, p. 388). Darwin also quoted from Huxley’s *Evidence as to Man’s Place in Nature* in *The Descent of Man* in relation to tracing the genealogy of human beings as diverging from the Old World division of the Simiadae. Much later, *Archaeopteryx* was used to illustrate the concept

of mosaic evolution, or selective evolutionary change on developmentally distinct parts of the body (Barnett 2020).

The anatomical dispute between Huxley and Owen had, in fact, ranged over more than simply the description of the first *Archaeopteryx* fossil. In 1857, Owen had presented three controversial assertions over some alleged differences between human and simian brains. Huxley responded by showing that none of these hypothesized differences – a third lobe, the posterior cornu of the lateral ventricle, and the hippocampus minor – were actually unique characteristics of human brains (Huxley 1863, pp. 134–135). This “Hippocampus debate” went on for some time as Owen refused to concede the basic point at issue and it spilled over from scientific journals into more popular media outlets such as *Punch* (Nocks 2008, p. 63). The fact that Huxley was vindicated in this debate provided further support for Darwin’s theory of evolution in a general sense, as Owen was known to be an evolution-skeptic.

## Conclusion

In terms of categorizing Huxley’s general approach to comparative brain anatomy, it can be seen as squarely within the Darwinian tradition of searching for evolutionary continuities in mental processes and structures between human beings and other animals (Shettleworth 2012, p. 529). In fact, given that the publication of Huxley’s *Evidence as to Man’s Place in Nature* had preceded the publication of Darwin’s *The Descent of Man* by a number of years and that Darwin included both Huxley’s own work (at least in the second edition) and employed his general approach to the subject in the book, the Darwinian tradition in comparative cognition should perhaps be re-labeled as the Huxleyite tradition, although, given Darwin overwhelming preeminence as a naturalist, this terminological shift is unlikely to become the accepted norm.

In the Huxleyite tradition, starting in the 1960s, Ralph Holloway conducted significant work on comparative brain size and structure differences,

with (in Holloway’s approach) changes in brain size being accompanied by parallel reorganizations of brain parts and systems (Gibson 1990, p. 97). Holloway developed an approach that he called paleoneurology using the endocasts of fossil crania in order to study the mosaic evolution of Hominin brains, which increased very significantly in size from the time of *Homo habilis* to that of *Homo sapiens*. According to Holloway, the appearance of the earliest *Homo* coincided with a major expansion of brain size and a reorganization of the frontal lobe, coincident with this being evidence of stone tool use (Holloway 2000, pp. 142, 148–149). This type of primate/human brain expansion had been recognized in bare outline at the end of the nineteenth century (Wallace 1889, p. 457). Paleoneurology and the study of endocasts can be seen as a direct extension of Huxley’s own comparative anatomy of cranial capacity, as can the relatively new subject of cognitive archaeology (Renfrew and Zubrow 1994), as has been recognized (Tobias 1971, p. 66).

In addition, Huxley’s *Evidence as to Man’s Place in Nature* can be seen as historically important in terms of laying some of the intellectual groundwork for the subsequent publication of Darwin’s own *The Descent of Man*. As has been explained, Darwin’s remark in the *Origin* that “Much light will be thrown on the origin of man and his history” was almost timid in the subtlety of its implication, and so “Others treated what Darwin feared to discuss” (Simpson 1972, p. 17): this “other” was preeminently T.H. Huxley. Darwin referred in the second edition of *The Descent of Man* to experiencing a “fiery ordeal” after publishing the first edition of the book (Darwin 1874 [1871], v), but some of this criticism had already been aimed at (or deflected by) Huxley’s earlier book, rather than Darwin’s own contribution on the topic, so the “fiery ordeal” of *The Descent of Man* was in all probability not as great as it would have been without Huxley. Huxley was, therefore, not only Darwin’s bulldog (his most effective advocate), but his intellectual point man as well, at least in applying the theory of evolution by selection mechanisms to the most contentious example of animal fabric of all: human beings.

## Tai Chimpanzees

Roman M. Wittig

Department of Primatology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

Tai Chimpanzee Project, Centre Suisse de Recherches Scientifiques, Abidjan, Ivory Coast

## Introduction

*Tai Chimpanzees* is a term used for a population of western chimpanzees (*Pan troglodytes verus*) located in the Tai National Park, which is situated in the southwestern region of Ivory Coast at the border to Liberia in West Africa. The *Tai Chimpanzees* are observed continuously since 1979 when primatologist Christophe Boesch and his wife Hedwige Boesch-Achermann established the Tai Chimpanzee Project (TCP). TCP ([www.taichimps.org](http://www.taichimps.org)) is dedicated to the research and conservation of the *Tai Chimpanzees* (Boesch and Boesch-Achermann 2000). In the beginning, Christophe Boesch habituated North group to the presence of human observers, a process that takes 5–7 years. Over many years he and his wife followed this community with the support from

only a few additional observers. TCP started to grow with Christophe Boesch's appointment as director of the Max Planck Institute for Evolutionary Anthropology in Leipzig, Germany, in 1997.

Several new chimpanzee communities have been habituated since then (Fig. 1a). After many years of surveying the area south of North group, habituation of South group started in 1994 in the hope for direct observation of intergroup encounters and female migration. However, even before South group was entirely habituated it became clear that one community of chimpanzees was ranging in between. Therefore, observers started to follow Middle group in 1997, which turned out

**Tai Chimpanzees, Fig. 1** Five chimpanzee communities habituated for research at the Tai Chimpanzee Project: (a) the position of each community within the research area, and (b) the community size of each community through time

The Tai Chimpanzee Project ([www.taichimps.org](http://www.taichimps.org)) – research on the wild chimpanzees (*Pan troglodytes verus*) in the Tai National Park, Côte d'Ivoire

to consist of 12 chimpanzees (Fig. 1b). As a result, TCP staff started in the year 2000 with the habituation of East group, allowing for two neighboring communities to study intergroup interactions from both sides. Finally, in 2014, TCP started the habituation of North-East group, a chimpanzee community bordering all other groups. After 33 years, Christophe Boesch handed over the responsibility for TCP to Roman Wittig in January 2013. To date (2017), TCP staff observes four neighboring chimpanzee communities (Fig. 1a) with about 150 individuals (Fig. 1b) and one group of sympatric living sooty mangabey (*Cercocebus atys*). An international team of local field assistants and international researchers is observing the *Tai Chimpanzees*.

The vested interest in behavior and cognition of chimpanzees is based on chimpanzees' similarity to humans. Chimpanzees, and their sister species the bonobo (*Pan paniscus*), are our closest living relatives. Our evolutionary paths have diverged only about 7–8 million years ago (Langergraber et al. 2012). The evolutionary closeness makes chimpanzees an ideal model species to investigate behavioral and cognitive adaptations of humans, since they allow us a glimpse into the past of our own species. This makes long-term projects like TCP an essential asset to the science community.

*Tai Chimpanzees* show a wide range of behaviors that appear to be very similar to that of humans. They use multiple tools to extract food, they cooperate during hunting of monkey prey and border patrols, they reconcile conflicts, they adopt orphans, and they developed cultures. Although these behaviors are not unique features of *Tai Chimpanzees*, but can be found also in other chimpanzee populations (Fig. 2), observations at TCP were either leading to the discovery or significantly contributed to our understanding of these behaviors. Much of the research on the *Tai Chimpanzees* has unraveled discoveries related to human evolution and animal cognition.

## Sociality and Bonds

Chimpanzees live in multi-male multi-female societies, with females migrating when they reach sexual maturity. They are typically seen as being male bonded, since males show typically higher levels of association and grooming than females, and female dominance hierarchy are usually not linearly structured. *Tai chimpanzees*, however, seem to be mixed sex bonded, showing differentiated relationships not only between males but also between females and between the sexes (Boesch 2009; Boesch and Boesch-

**Tai Chimpanzees, Fig. 2** Location of the Tai Chimpanzee Project and other long-term chimpanzee research sites across Africa in relation to the distributions of the four chimpanzee subspecies

Achermann 2000). This classification of *Tai chimpanzees* as being mixed sex bonded has several reasons. First, *Tai* females invest not only into differentiated relationships with females and males (Wittig and Boesch 2010a) but also show a linear dominance hierarchy in females (Wittig and Boesch 2003a), indicating that social relationships with and amongst females matter. Second, females in *Tai* range throughout the entire home-range of the community and do not inhabit satellite or neighborhood territories (Lehmann and Boesch 2005), as has been reported for many other study sites (Pusey and Schroepfer-Walker 2013). Third, *Tai* females can exhibit a certain choice in choosing their mating partners (Stumpf and Boesch 2006) preferring mating partners which have shared meat with them beforehand (Gomes and Boesch 2009). Finally, male violence towards females of the same community is much lower in *Tai*, where males have never been observed to commit intracommunity infanticide, killing the infants of females belonging to the same social unit, while this has been observed several times in other chimpanzee communities (Wilson et al. 2014). A result of this might be the higher survival probability of chimpanzee youngsters in *Tai* during periods without disease outbreaks compared to eastern chimpanzees (Wood et al. 2017). Thus, females in *Tai* might be able to bond with the local males, range over the same territories, and exhibit differentiated mating choices because they do not need to worry about that local males would kill their infants.

## Reconciling Conflicts

*Tai Chimpanzees*, like other social animals, face the dilemma of group living. On the one hand, they need to cooperate with group members in order to reduce predation risk, to increase territory defense or exploitation of food sources. At the same time, they compete with the other group members over mating partners, food, or shelter. Facing a conflict of interest *Tai Chimpanzees* need to decide whether they escalate the conflict into aggression, winning the resource but damaging the cooperative relationship with the opponent or

to leave the resource to the opponent (Wittig and Boesch 2003b). Once the conflict is escalated to aggression the relationship to the opponent is damaged and tolerance levels are disturbed (Wittig and Boesch 2005). In this case reconciliation, the friendly interaction between former opponents after aggression, can restore tolerance levels to normal and repair the relationship between the opponents to allow future cooperative interactions (Wittig and Boesch 2005).

Approaching the former opponent to reconcile, however, is not possible all the time. Sometimes fear about reemerging aggression is making a friendly direct contact of former opponents impossible. There is, however, a solution to the problem. In such cases, *Tai chimpanzees* seek friendly contact with the friend of their former opponent or friends seek friendly contact to the opponent of their friend. The friendly contact with the former opponent's friend functions like reconciliation between the opponents, but without them needing to have direct contact (Wittig and Boesch 2010b). This friend-mediated reconciliation requires that *Tai chimpanzees* know who is friend with whom. Otherwise the friendly contact with the opponent's friend would not show any effect on the tolerance level between the opponents.

## Hunting and Food Sharing

*Tai Chimpanzees* are specialized hunters of monkey prey. They regularly hunt for western red colobus (*Procolobus badius*) and western black-and-white colobus (*Colobus polykomos*). During these hunts *Tai Chimpanzees* coordinate their activity and show high levels of group cooperation. In most of these hunts they coordinate their activity in time and space, while engaging in different roles (Boesch and Boesch 1989). A driver climbs up in the tree next to the monkeys and starts slowly moving towards them. The monkeys start fleeing into the next tree. Blockers sitting in other trees close by watching the monkeys and block their escape routes. This way they channel the movement of the monkeys and make them to move towards a certain direction. In this certain direction a hidden catcher is ready for

the ambush. Once the monkeys reach the tree of the catcher, he makes his move, grabs one of the monkeys, and drags the prey to the ground, where the chimpanzees come together in to feed on the meat.

The meat of the monkey is usually distributed among the hunters (Fig. 2). From there it is shared with friends and friends-to-be. Why “friends-to-be,” because the sharing of food is strongly linked to high levels of urinary oxytocin. Oxytocin is a hormone known to facilitate bonds between individuals. It seems that sharing food allows individuals to build new friendships and to maintain existing bonds (Wittig et al. 2014). While in some other populations meat sharing is mainly based on avoiding harassment (Gilby 2006), *Tai* chimpanzees share meat more often with individuals that were involved in the hunt (Boesch 1994) and in exchange for agonistic support (Gomes and Boesch 2011). The latter has been described similarly in other chimpanzee populations (Mitani and Watts 2001). It seems that meat sharing, or even sharing of food in general, may reflect the wish of a *Tai* chimpanzee to make a friend or coalition partner.

## Tool Use and Culture

*Tai* Chimpanzees are famous for their nut cracking technique. They employ a hammer and anvil principle to crack open the shells of several nut species (e.g., *Coula edulis*, *Panda oleasa*, *Detarium senegalense*; Fig. 3). *Tai* Chimpanzees do so by placing the nut on a solid anvil, e.g., a root or a rock, most of which are used since many years so that the nuts have left an imprint over time, and hit the nut with a wooden club or a stone hammer until the shell breaks open (YouTube channel of the *Tai* Chimpanzee Project: Dilly cracks nuts). If the nut is not hit hard enough, the shell does not crack, if the nut is hit too hard, the kernel is smashed. Skilled nut crackers adjust the force so the nut shell open with one or two hits and they can consume the kernel. Infants may need many years before they are able to do so. Sometimes *Tai* Chimpanzees may be unable to remove the entire

**Tai Chimpanzees, Fig. 3** Coula nut cracking site with hammer and anvil in the *Tai* National Park © Roman M Wittig, TCP

kernel from the shell. Then they may break a stick into the right length of a spooning tool and spoon the rest of the kernel out.

Although nuts like *Coula edulis* are present in many chimpanzee populations, they are only cracked west of the river Sassandra in Ivory Coast. Behavioral variation like this, independent of genetic or ecological variation, has been termed tradition, and the sum of all such variation as culture. Chimpanzees show cultural variation when comparing between populations across Africa with *Tai* Chimpanzees being described as the nut cracking culture (Whiten et al. 1999). However, *Tai* Chimpanzees exhibit also cultural variation between neighboring communities.

At the beginning of the Coula nut season, the nuts have harder shells and they are cracked and consumed in the tree. *Tai* Chimpanzees use stone hammers, which are easier to transport into the tree and better to crack the hard shell of the fresh nut. With proceeding time during the nut season, the shell drying out and loses its hardness. The chimpanzees use more and more wooden clubs to crack the nuts, which are much more abundant than stones. This makes life easier for them and long searching for appropriate tools is not slowing them down anymore. *Tai* Chimpanzees follow this rule in north and east group, but not in the neighboring south group. In south group they continue to use stones throughout the entire Coula nut season, although stones are not more abundant in

the south group territory than in the others. The difference in the nut cracking behavior between south group and the two others is based on cultural differences (Luncz et al. 2012).

Immigrating females even conformed to the culture of the south group in *Tai*. Females coming from a natal group that belong to the stone and wood hammer culture adopted the stone hammer culture of the south group after immigration (Luncz et al. 2015). Within one nut cracking season they had adopted the culture and did not change to wooden hammers back anymore. This suggests that conformity with the group culture is an important feature of group identity among the *Tai Chimpanzees*.

## Adoptions

Adoptions are a chimpanzee universal, but in *Tai* we were able to observe a large number of adoptions carried out by either, female and male chimpanzees. When mothers die before their offspring have reached adulthood (with 15 years), they leave an orphan behind. With an inter-birth-interval of about 5.5 years (Boesch and Boesch-Achermann 2000), dead parous females leave usually at least one dependent offspring. Children that are orphaned before they have reached 5 years of age, while they are completely dependent on their mother, have almost no chance to survive. Generally, one can say, the younger the offspring is the lower the probability for it to survive without the mother.

In *Tai* about 50% of the orphans are adopted by other group members (Boesch et al. 2010). Adopters carry the orphan, share food and night nests with them, support the orphans in aggressive interactions, and wait or search for them. Interestingly, in *Tai* adopters can be both, close kin (in form of siblings or fathers) or unrelated to the orphan. Whether the adopters are kin or non-kin, adoption increases the orphan's chance to survive longer. The film *Chimpanzee* (2012), produced by Disney Nature, is telling the story of an adoption, featuring the orphan Oscar that is adopted by the alpha-male Freddy. The footage was taken of the *Tai Chimpanzees* and contains the adoption of

Victor by the old male Freddy in TCP's East group after the death of Victor's mother Vanessa in 2008. Freddy has been ever since somebody who adopted many other infant orphans and was able to help quite a number to survive for many years.

## Conservation

Western chimpanzees are critically endangered. Over the last 20 years, we lost more than 80% of the population of *Pan troglodytes verus* in the world (Kühl et al. 2017). Estimates suggest that between Ghana and Senegal there are about 35,000 western chimpanzees left. The *Tai* National Park is the largest remaining primary rainforest in West Africa and is, with its 4540 km<sup>2</sup>, home to an estimated 300 chimpanzees. The population is under pressure from poaching, habitat destruction, and illegal mining.

Diseases are an additional survival hazard for *Tai chimpanzees*. During the last 35 years, *Tai chimpanzees* have been victims to a large number of different diseases, e.g., Ebola (Le Guenno et al. 1995), anthrax (Hoffmann et al. 2017), respiratory diseases (Köndgen et al. 2008). While some originated in the forest, others have human origin. Due to the chimpanzees close genetic relationship, there is a high possibility of transmitting respiratory diseases from humans to chimpanzees. Since 2009, therefore, TCP has strict hygiene rules and employs 5 days quarantine for anybody who is going to observe the chimpanzees or mangabeys (Grützmacher et al. 2017). These rules have been adopted by IUCN (International Union for Conservation of Nature) as best practice for the research and tourism with great apes and prevented since then cases of lethal respiratory outbreaks.

Research conducted by the *Tai Chimpanzee Project*, however, is not only enlarging our knowledge about chimpanzees and human evolution but has also a direct impact on the protection of the chimpanzees and other mammals in the research area. Using National Park wide survey data

showed that illegal human activity is the lowest around the research and ecotourist areas, leading to the highest animal densities for chimpanzees, monkeys, and other mammal species in the research and ecotourist areas (Campbell et al. 2011). This correlation between research area and animal density shows the crucial conservation effect of long-term research sites like the *Tai Chimpanzee Project*.

## Conclusion

When comparing *Tai Chimpanzees* to other chimpanzee populations (Fig. 2) we find some pattern that seem to differ. *Tai Chimpanzees* build friendships between males, between females, and between males and females. If unable to reconcile the conflict with the former opponent, they seem to have the ability to repair the damage done by the aggression when “reconciling” with a friend of the former opponent instead. Although *Tai Chimpanzees* are competitive and violent to the rival groups (neighbors), they do not seem to commit killings within their own group. All these features make the *Tai Chimpanzees* a population of chimpanzees with lower violence and a higher degree of mixed sex bonding compared to other long-term sites. Whether this is a *Tai* trait, a western chimpanzee characteristic, or features that can develop anywhere under certain ecological conditions remains to be investigated.

The presence of the *Tai Chimpanzee Project* is vital for the survival of the *Tai Chimpanzees*. Without a long-term investment in research, the sustainable management of the Park as a protected area seems impossible. Research at the *Tai Chimpanzee Project* incorporates the three pillars of the millennium declaration by the UN on sustainability. First, the social development in form of providing knowledge for society and education for local human population; second, the economic development in form of salaries, health insurance, and microloans for local staff; and third, the environmental protection, in form of effective safeguarding of the only irreplaceable protected area for biodiversity in West Africa, the *Tai National Park* (Saout et al. 2013).

The word “Tannin” originally refers to the early use of oak and other barks in tanning animal hides into leather. Tannins (commonly referred as tannic acid) are water-soluble polyphenols commonly distributed in plants (The Editors of Encyclopedia Britannica

2016). The presence of tannins has been noted in both gymnosperms as well as angiosperms. The plant families that have been found to produce tannins are *Actinidiaceae*, *Anacardiaceae*, *Aceraceae*, *Burseraceae*, *Bixaceae*, *Combretaceae*, *Dipterocarpaceae*, *Ericaceae*, *Grossulariaceae*, and *Myricaceae* in case of dicots and *Najadaceae* and *Typhaceae* in case of monocots (Mole 1993). Additionally, tannins have been found to occur in numerous plant parts for instance: roots, barks, wood, fruits, and leaves. Apart from these they are also reported in galls resulting from the insect attacks. They can be present in any form ranging from a group of pale-yellow to light-brown amorphous powdery substances, flakes, or a spongy mass (The Editors of Encyclopedia Britannica 2016).

Tannins have high molecular weights ranging from 500 to 20,000 and possess low nutritional value (Swain and Bate-Smith 1962). Due to the presence of a high number of hydroxyls and other suitable groups (like carboxyls), they have the tendency to bind and precipitate proteins, amino acids, and alkaloids.

Tannins can be broadly classified into the following categories:

1. **Hydrolysable tannins:** Tannins that form gallic or ellagic acids on heating with hydrochloric or sulfuric acids are termed as hydrolysable tannins or pyrogallol-type tannin. These tannins are generally present in different vegetable plants like myrobalan (*Terminalia chebula*), sumac (*Rhus coriaria*), gallnuts (*Quercus infectoria* and *Rhus semialata*), Aleppo gallnuts (*Andricus kollari*), tara pods (*Caesalpinia spinosa*), chestnut wood (*Castanea sativa*), and oak wood (*Quercus robur*, *Quercus petraea*, and *Quercus alba*) (Haslam 1989; Hemingway and Laks 2012).
2. **Condensed tannins:** The polymers resulting from the condensation of the flavans are called as condensed tannins. Sugar residues are absent in the condensed

tannins. They are present in uebracho wood (*Schinopsis lorentzii*), mimosa bark (*Acacia mollissima*), grape seeds (*Vitis vinifera*), pine barks, and spruce barks (Haslam 1989; Ping et al. 2011).

3. **Pseudotannins:** Pseudotannins unlike the hydrolysable and condensed tannins do not change color during Goldbeater's skin test. Furthermore, they cannot be used as tanning compounds and are present in Rhubarb, acacia, catechu, tea, coffee etc. (Kar 2003).

**Properties of Tannins:** Tannins function as protectors and pesticides in plants. The astringent taste of the tannins causes a dry and pucker feeling in the mouth similar to that felt after the consumption of tea, unripened fruit, or red wine. This unpleasant feeling wards off the predators and the insects (McGee 2004). Tannins are extensively used in tanning leather, dyeing fabric, making ink, and in various medical applications. Apart from protection, tannins are also involved in the regulation of the plant growth (Corcoran et al. 1972).

Studies have shown that tannins possess anticarcinogenic and antimutagenic activity. These polyphenolic compounds are known to reduce the level of reactive oxygen species present in the body. This anti-oxidative property of tannins is assumed to be the underlying reason for its anti-cancer property. Many reports have been published claiming the antimicrobial nature of tannins against fungi, bacteria and viruses. They are also known to possess certain physiological properties like accelerating the clotting of the blood, reduction in the levels of the serum lipid and blood pressure, modulation of immune response, and also causing liver necrosis. They function as good preservatives and are also used for clearing Japanese sake. Tannins have the ability to produce different colors with ferric chloride. Along with the use in the formation of corrosion free primers, it is also used in wood and particleboard adhesives (Chung et al. 1998).

## Conclusion

Tannins are polyphenolic plant-based compounds playing a pivotal role in the protection of the plants. Although, the tannins are low in nutritive value, they have a wide range of applications in the human health as well as in combating diseases. More research in this field would unravel the true potential of tannins and uncover more applications for the betterment of the human health.

Tapetum is structurally and functionally diverse unistrata layer of universal occurrence in the microsporangia of all land plants that chiefly serves as a nutritive tissue for developing male gametophytes (Dickinson and Bell 1972, 1976; Sporne 1973; Pacini 1997; Pacini et al. 1985; Huysmans et al. 1998). The tapetum is better known in higher plants (gymnosperms and angiosperms) than in lower plants (bryophytes and pteridophytes) as its activities are less frequent in lower plants than in higher plants (Dickinson and Bell 1972, 1976; Pacini et al. 1985; Parkinson and Pacini 1995). On the other hand, compared to their aquatic ancestors, early land plants had well-protected reproductive structure, the loculus – a liquid-filled cavity that occurs within the microsporangia of many groups in which the spores or pollen grains develop and ripen. This cavity, loculus, is bordered by a tissue of sporophytic origin, i.e., tapetum (Pacini et al. 1985).

However, the origin, development, and specific functions of tapetum vary across all plant

divisions; therefore it has been considered as key reproductive character to investigate evolutionary lineages' especially among higher plants (Endress 2001; Furness and Rudall 1998; Furness and Rudall 2001; Gorelick 2001; Taylor et al. 2012).

The natural life of the tapetal cells too varies among plants and depends on the length of pollen development. In angiosperms, it generally ranges from few days to few weeks (Pacini et al. 1985). In gymnosperms, the tapetal cells are comparatively long lived and can persist up to 6 months (Cecich 1984). In pteridophytes too, the life span of tapetal cells differs from a few days to few weeks (Kelley and Doyle 1975; Mogensen 1978).

### Structure, Histochemistry, and Origin of Tapetal Cells

Tapetum, most often a single cell layer, is quite distinguishing among angiosperms being an integral element and the innermost layer of anther wall that separates the anther wall and the sporogenous tissue within the anther (Fig. 1). The mature anther wall comprises an epidermis (E) followed (on the inside) by a layer of endothecium (END), two- or three-celled middle layers (ML), and a single cell layer tapetum (TA) that attains its maximum development at the tetrad stage

of microsporogenesis (Goldberg et al. 1993; Bhatnagar et al. 2015).

The tapetal cells are characterized by relatively larger cells in size with thin cell walls, dense cytoplasm consisting numerous endoplasmic reticulum, Golgi bodies, plastids, mitochondria, and a prominent nuclei (Moss and Heslop-Harrison 1967; Mizelle et al. 1989; Bedinger 1992; Polowick and Sawhney 1993). Binucleate, tetranucleate, multinucleate or polyploid tapetal cells have also been observed in some species (Bhatnagar et al. 2015).

The parietal origin of the tapetum is universal in occurrence; however, dual origin of tapetal cells has been observed in most of the angiosperms (Davis 1966; Periasamy and Swamy 1966; Bhandari and Khosla 1983; Bhatnagar et al. 2015). It has been observed that among angiosperms, most often the tapetal portion toward outside is contributed by the parietal layer, and the inner portion is derived from the connective tissue (Fig. 2). During differentiation of anther, a periclinal division occurs in the archesporial cells that give rise to outer primary parietal cells and inner primary sporogenous cells (Fig. 2). The inner primary sporogenous cells (spl) divide to secondary sporogenous tissue and ultimately differentiate into microsporocytes (Fig. 2). The outer primary parietal cells (ppl)

**Tapetum, Fig. 1** Transverse section (TS) of anther showing anther wall layers [epidermis (E), endothecium (END), middle layers (ML), tapetum (TA)] and developing sporogenous tissue (ST)

**Tapetum, Fig. 2** Dual origin of tapetum. (Source: Davis 1966; Bhatnagar et al. 2015)

undergo another periclinal division to give rise to two sets of secondary parietal cells (spl1 and spl2). The inner secondary parietal cells (spl2) differentiate into tapetal cells (Fig. 2); these cells become distinct gradually and enclose sporogenous tissue or microspore mother cells, completely. On the other hand, the outer secondary parietal cells (spl1) divide further and differentiate into middle layers and endothecium cells ((Fig. 2; Davis 1966; Bhandari 1984; Sanders et al. 1999; Bhatnagar et al. 2015).

In a few species such as *Alectra thomsoni*, the tapetal cells of different origin varied morphologically, i.e., dimorphic tapetum, where tapetal cells are much smaller toward outside than those toward inside (Bhatnagar et al. 2015). On the other hand, homogenous tapetum occurs in the members of triticales where tapetal cells originate solely from the parietal layer (Bhandari and Khosla 1983).

## Types of Tapetum

In angiosperms, different types of tapeta were reported, but two very basic types, viz., secretory

type and amoeboid type, of tapetum have been documented continually by various botanists on the basis of tapetal cell's behavior (Fig. 3; Maheshwari 1950; Echlin and Godwin 1968; Mepharm and Lane 1968; Pacini et al. 1985; Pacini 1997; Rowley et al. 1992; Pacini 1997; Furness and Rudall 2001; Pacini 2010).

The secretory tapetum, also known as cellular, glandular, non-syncytial, and parietal tapetum, comprised of long persistent cells which do not invade the locule itself and secrete materials into the locule during pollen development, e.g., *Alloe*, *Helleborus*, *Nigella*, *Rumex*, and *Victoria* (Furness and Rudall 1998; Taylor et al. 2012).

In the amoeboid tapetum also known as intrusive, invasive, periplasmodial, and syncytial invasive tapetum, the protoplast of tapetal cells migrates into the locule having indirect contact with developing spores by forming a periplasmodium, e.g., *Alisma*, *Arum*, *Butomus*, *Tradescantia*, *Typha*, etc. It was also revealed that the amoeboid tapetum rarely occurs in gymnosperms (Pacini and Juniper 1983; Pacini et al. 1985; Furness and Rudall 1998; Furness and Rudall 2001).

**Tapetum, Fig. 3** Types of Tapetum

An intermediate type of various tapeta, cyclic invasive tapetum, has also been reported where the tapetal cells invade the locule initially but later retreat back to the anther wall, e.g., *Canna* and *Nymphaea* (Tiwari and Gunning 1986; Rowley et al. 1992; Hess and Hesse 1994; Furness and Rudall 1998; Furness and Rudall 2001).

It has been reported that the secretory tapetum being the ancestral condition is the predominant form among all the land inhabited plants (Pacini et al. 1985; Furness and Rudall 2001; Pacini 2010). On the other hand, it has been revealed that the amoeboid tapetum type rarely occurs in gymnosperms and it was more prevalent among monocotyledonous plants than dicotyledonous plants that has been shown also evolved independently many times in early divergent angiosperms (Pacini et al. 1985; Furness and Rudall 2001). The cyclic invasive tapetum type has been shown to be an intermediate type between secretory and plasmodial one that has evolved independently in the species of family Annonaceae, Monimiaceae, Nymphaeaceae, and Winteraceae (Furness and Rudall 2001).

### Developmental Regulation and Molecular Biology of Tapetal Cells

Development of the tapetum is highly regulated and programmed during anther development

(Schrauwen et al. 1996; Owen and Makaroff 1995; Sanders et al. 1999). The tapetum is identified at anther stage 5 and undergoes programmed cell death in stage 10 and then release the contents for further pollen wall development and mature pollen formation at stage 12 in *Arabidopsis thaliana* (Owen and Makaroff 1995; Sanders et al. 1999).

As far as the expression of tapetum-specific genes and their protein products is concerned, it is tightly regulated in time that turned on and off at certain specific points during tapetal life span and participate in the developmental regulation of male gametophyte (Staiger and Apel 1993; Staiger et al. 1994; Schrauwen et al. 1996; Ma 2005).

*Tapetum determinant1* (TPD1) and *excess microsporocytes1* (EMS1)/*extra sporogenous cells* (EXS) genes have been shown to play a pivotal role for tapetal cell specialization (Zhao et al. 2002; Yang et al. 2003; Jung et al. 2005). In the absence of TPD1 or EMS1/EXS, the inner secondary parietal cells develop into microsporocytes instead of tapetal cells. It has also been revealed that the TPD1 and EMS1/EXS gene (s) may function in the same developmental pathway, as the *tpd1* mutant was phenotypically identical to the *ems1/exs* mutant (Canales et al. 2002; Zhao et al. 2002; Yang et al. 2003; Ma 2005).

Moreover, several transcription factors regulating tapetum development and pollen formation

have also been reported as *dysfunctional tapetum1* (*DYT1*). Defective *DYT1* results in a premature vacuolation of the tapetum and the absence of pollen (Ma 2005; Zhang et al. 2006). Besides, *tapetal development and function1* (*TDF1*) too encodes a putative R2R3 MYB transcription factor. Defective *TDF1* results in a dysfunctional tapetum with irregular cell division and absence of pollen in both *Arabidopsis* and rice (Zhu et al. 2008; Cai et al. 2015). *AtMYB103/MS188* also plays an important role in tapetum development, callose dissolution, and exine formation in anthers (Higginson and Parish 2003; Zhang et al. 2007; Zhu et al. 2010, 2011).

## Role of Tapetum

- Nurture, development, and maturation of pollen grains: The tapetal cells are of substantial importance as they essentially nurture the sporogenous meiotic cells during microspore development in anthers and transform the developing microspores into viable pollen grains (Maheshwari 1950; Heslop-Harrison 1968a, b; Pacini et al. 1985; Nave and Sawhney 1986; Sawhney and Nave 1986; Chaudhury et al. 1994; Zhang et al. 1994).
- Formation of pollen wall and formation of exine precursors: Synthesis of sporopollenin precursors (Vithanage and Knox 1980; Bhandari 1984).
- Secretion of polysaccharides and production of orbicules and locular fluid (Heslop-Harrison et al. 1973).
- Secretion of specific substances for pollen protection and pollination: Production and release of callase to dissolve the callosic envelope, formation of viscin threads, tryphine, and pollenkitt to protect pollen from UV radiation (Mephram and Lane 1970; Hesse 1981, 1984; Pacini et al. 1985).
- Secretion of some specific proteins, enzymes, and inhibitory substances: Many specific proteins, responsible for pollen allergy, are secreted by tapetum.
- Regulation of pollen fertility (Izhar and Frankel 1971; Grant et al. 1986; Liu et al. 1987; Chaudhury et al. 1994; Zhang et al. 1994).

## Introduction

Molecular biology is a subject dedicated to understanding the microscopic phenomena that drive life. To engage in this field, a study will begin on a biological process. Multiple proteins, RNA and DNA sequences, and other molecular machinery are involved in any number of processes – discovering what each component does in a system can be a daunting task. One of the clear ways to identify the functionality of a gene is to generate a “knock-out” or a cell line (or animal line) without the gene in question. A knock-out line helps to answer a number of questions, for instance; does the system still function in the same way? If not, how is it failing? And what is the phenotype in the knock-out? In turn, these answers lead to new questions, and the life cycle of science repeats itself.

Due to the detrimental, sometimes fatal phenotypes produced from knock-outs, these experiments are done in model organisms and cell lines. Common model organisms are mice, rats, *Drosophila* (fruit flies), yeast, and zebrafish, among others. In the case of mammals (mice), modern techniques are used to target a mutation in embryonic stem cells (ESCs). The common method of creating a mutant mouse line is as follows – the desired mutant ESC is injected into the inner cell mass of a blastocyst. This leads to the generation of chimeric mice, which are crossed with wild type mice to produce progeny, some of which are heterozygous for the mutation of interest. Finally, these heterozygous mice are crossed; some of their progeny are homozygous for the mutant gene. There are a number of ways to introduce a mutation to an ESC; this passage will explore the variety of techniques that have been refined to target genes.

double strand breaks on the DNA. While this is an important step for ensuring genetic diversity during meiosis, HR is also important in repairing damaged DNA, the process utilized in gene targeting HR. In order for HR to take place, large stretches of the repair DNA must be identical; when using HR for gene targeting purposes, a plasmid must be introduced to an early stage cell – a fertilized egg or ESCs are ideal. The plasmid introduced to the early stage cell must contain a large amount of homology to the region being targeted. The plasmid will otherwise vary depending on the experiment – it could cause a slight insertion, a deletion, or a point mutation (Rocha-Martins et al. 2015).

The resulting gene targeted cell line is a rare event when using HR, as it is dependent on a double-strand break happening. To bypass the difficulties of finding the proper cell line, many experiments using this method include either a selection marker or a reporter marker. A selection marker is an additional gene that contains the resistance of an antibiotic. Therefore, the plasmid that knocks out the gene of interest also introduces, for instance, a neomycin resistance marker. When treated with neomycin, the cells that survive have successfully incorporated the new sequence (including the knock-out of the gene of interest and inclusion of the neomycin resistance marker) via HR. The other means to detect a successful mutation is to include a reporter marker on the plasmid with the target sequence. Reporter markers are genes that are measurable in some way. For instance, the green fluorescent protein is a frequently used reporter as it makes the cell lines it is introduced to glow. These selection and reporter marker methods are utilized in other gene targeting techniques as well (methods described below), as they improve efficiency of these experiments.

## Homologous Recombination

Gene targeting became feasible in the 1980s upon the advent of microinjection technologies and the understanding of biological process homologous recombination (HR). HR is a process in which portions of like chromosomes are exchanged after

## Zinc Finger Nucleases

Zinc finger nucleases (ZFNs) are tools used to target mutations. These chimeric proteins are made of two parts, the cleavage domain of the FokI restriction enzyme (a protein that cuts DNA at a particular site) and C2H2 tandem zinc-fingers

(a protein domain that binds DNA). The FokI cleavage domain is able to cut any sequence, so long as there is an enzyme on both strands (requiring two of these targeting proteins). C2H2 zinc-fingers (there are two cysteines and two histidines that bind zinc and form the 3D shape of the domain) bind triplets of DNA and are modular. Subsequently, with different mixes of zinc fingers, different sequences can be targeted (Urnov et al. 2010). Therefore, with two designed chimeric ZFNs, a cut can be made on a targeted DNA strand, which can lead to the nonhomologous end joining (NHEJ) pathway. The NHEJ pathway is not specific and can cause random mutations, which could be insertions or deletions (InDels). With the addition of a plasmid or donor DNA with homology, homology directed repair (HDR) can be initiated to yield a specific mutation. A limitation of ZFNs is that zinc fingers do not always bind the triplet they are predicted to bind, and may not target properly (Rocha-Martins et al. 2015) (Fig. 1).

## TALENs

Transcription activator-like effector nucleases (TALENs) are another modular tool used to target mutations. Like ZFNs, they use a chimeric protein with FokI to cleave. Their DNA binding activity is due to their TALEs, which are proteins that originate from bacteria. TALEs are repeat proteins that have two amino acids in the middle of their sequence, which controls their DNA binding;

these two amino acids bind one nucleotide (Miller et al. 2011). Subsequently, they are much more specific than ZFNs and deal with less off-target effects. Like ZFNs, they can undergo either the NHEJ pathway or HDR pathway, depending on the absence or presence of repair DNA.

## Conditional Knock-outs and Recombinase Systems

Conditional knock-outs are targeted mutations that are knock-out only upon the introduction of a catalyst that causes a deletion. The advantages of this are many. Conditional knock-outs became essential for transgenic organisms; many mutations are early embryonic lethal and cannot be studied as a traditional knock-out line. The most common conditional knock-out system used currently is the Cre-LoxP system. The Cre-LoxP originates from the bacteriophage P1 – it is their system utilized for recombination. The system requires two LoxP sites outside a gene of interest and the addition of Cre recombinase proteins. Cre recombinase is a protein that recognizes and binds to the locus of crossing-over of P1 (LoxP). A LoxP site has two 13 nucleotide palindrome sequences which flank an 8 nucleotide sequence which dictates the orientation of the site. Four Cre recombinase proteins bind each site (each palindrome). These proteins then mediate the formation of a Holliday junction (a structure in which homology between the strands initiates a four-way binding, which in this setting

Targeted Mutation, Fig. 1 Modular Nucleases

makes a loop) in the DNA (Branda and Dymecki 2004). If the LoxP sites face the same direction, the content between them is cut out and becomes its own loop, while the genomic strand now has one LoxP site. If the LoxP sites face opposite directions (facing each other), the addition of Cre will induce an inversion of the sequence between the sites.

When making cell lines, the LoxP sites need to be targeted to the proper sites (perhaps through one of the methods described in this section). The Cre recombinase can be added through a number of ways, although many introduce a plasmid (or target a sequence to add it in permanently). Typically, the Cre recombinase is under control of a tissue-specific promoter so the recombination does not happen until the proper time point, although some Cre recombinases are under the control of a promoter that is only active in the presence of a ligand. Either way, this system allows for a controllable knock-out, which is critical when studying genes that can cause lethal phenotypes at different time points (Fig. 2).

### CRISPR/Cas9

The CRISPR/Cas9 system has become a prominent tool for editing genomes. Clustered regularly interspersed short palindromic repeats (CRISPR) are originally found in bacterial genomes as a means of genome defense against viral elements. The various Cas endonucleases – which use CRISPR sequences to recognize DNA – cut the

viral elements, which then are incorporated into the genome, so other Cas proteins can effectively recognize and cleave viruses. This is essentially a form of innate immunity in bacteria. The system was reworked so that a single plasmid can express Cas9 and harbor the scaffolding and targeting elements – the guide RNA (gRNA), which is a combination of two RNAs from the native bacterial system. The Cas9 protein contains the gRNA in it, which is 20 nucleotides long. Just outside where the gRNA binds in the DNA is a NGG nucleotide sequence, referred to as a protospacer adjacent motif (PAM), which is needed for Cas9 to recognize a cut site. The gRNA recognizes and attaches to the binding motif, allowing the Cas9 protein to cut. At this point, the reaction can either undergo NHEJ or HDR depending on the absence or presence, respectively, of repair DNA (Ran et al. 2013). The CRISPR/Cas9 system has been categorized as more efficient than ZFNs and TALENs, as unlike those protein-DNA binding methods, CRISPR/Cas9 is a RNA-DNA binding method, allowing an accurate binding reaction and the capability of targeting multiple genes effectively (something that ZFNs and TALENs are unable to do). The main drawback of CRISPR/Cas9 is that it tolerates up to three mismatches in the sequence it binds, and is therefore susceptible to off-target reactions and mutations. Still, due to its efficiency, ability to be customized, and ability to target multiple sites at once, CRISPR/Cas9 has become an important tool for molecular biologists (Fig. 3).

**Targeted Mutation, Fig. 2** Conditional Knockouts

**Targeted Mutation, Fig. 3** CRISPR/Cas9

## Lentiviral Vectors

Another form of targeting a mutation (although specifically for insertions) are lentiviruses, which have become a common tool for introducing new genes due to their high efficiency of integration. As retroviruses, lentiviruses reverse transcribe their genetic content into a host cell's genome. With the advent of plasmid design, custom lentiviruses can be generated that do not integrate the viral packaging genes – therefore, a lentivirus can carry and integrate genes of interest (Sakuma et al. 2012). An example of their use would be to transduce a lentivirus that carries *gene x* into a *gene x* knock-out cell line and see if any detrimental phenotypes of the knock-out are rescued. There is a major detriment to this system; the gene of interest could integrate at any site across the genome, and therefore the surrounding chromatin state will vary greatly between subclones from one experiment. This, in turn, leads to variations in expression patterns.

## Conclusion

As gene targeting methods become more advanced and refined, they progress towards the potential to be used clinically; however, the number of off-target effects makes such use prohibitive. For now, they remain one of the most prominent and powerful tools at the disposal of molecular scientists. The ability to observe molecular systems with and without key components, to recreate disease states in ESCs, and to control knock-outs and knock-ins in a temporal fashion in animal models

is invaluable. The tools and systems described in this section have all allowed for rapid scientific progress and discovery.

## Taste Aversions

Andrés Molero-Chamizo  
Department of Psychology, University of Huelva,  
Huelva, Spain

## Introduction

Some vertebrates and invertebrates share a type of learning that is critical for survival. These animals can associate a relatively novel taste with the

effect of poisoning, resulting in a learned or conditioned taste aversion (CTA) to the respective flavor or, by generalization, to similar flavors (Scott 2011). In the following exposures to the conditioned taste stimulus, the animals would consider that stimulus dangerous because they would have learned that it induces gastrointestinal malaise and, if the conditions of survival allow it (i.e., if there is another food available), they would reject that stimulus. Acquired aversion does not only mean rejection or avoidance of the taste stimulus in the future but also involves a change of its hedonic value because it would be perceived as an unpleasant stimulus. This process preserves the life and, therefore, is an adaptive learning, especially for omnivorous species, such as the human beings, which feed on all potential food. In these species, the acquisition of CTA is vital because the learned aversion shall reduce the probability of re-experiencing the toxic effects of a harmful substance. In those situations in which the animals decide to try the aversive stimulus (e.g., with no other option to feed on), the taste aversion would be extinguished if no further poisoning consequences result from the ingestion.

Since the middle of the last century, all these processes have been studied in the laboratory to understand the behavioral mechanisms of associative learning, and standard paradigms have been established to explore the peculiar characteristics of the acquisition of CTA and other related learning complex phenomena (Bernstein 1999). Moreover, the brain substrates and cellular and molecular mechanisms behind the formation of taste aversions and taste memory are being intensively investigated to understand the neurobiological bases of this essential learning. The typical processes and characteristics of the acquisition of taste aversion and taste memory will be described in the next section. In the following sections, the well-established laboratory paradigms to induce CTA in animal models as well as the known neurobiological mechanisms of the acquisition of CTA and taste memory will be outlined. Final considerations and conclusions will be exposed in the last section.

## Processes and Mechanisms of Taste Aversion

As mentioned above, the acquisition of taste aversion is an evolutionary advantage for many animal species. The knowledge of the processes and mechanisms involved in the acquisition of CTA and taste memory formation is essential to understand the common aspects of evolution and learning between species. CTA can be easily reproduced in animal experimentation studies, and because of its characteristics, it is a powerful tool to study the universal mechanisms of learning and memory.

CTA is a unique learning process because it includes three simultaneous associative learning characteristics that have only been observed together in this form of learning. First, taste aversion can be acquired after a single trial of association between the taste stimulus and visceral disease (Bures 1998b). Second, there is a biological predisposition to associate gastrointestinal malaise with taste stimuli, which can also be associated with external stimuli but with remarkably less associative strength. In rats, for example, it has been shown that the association between taste and external signals is weak (García and Koelling 1966). The third characteristic refers to the delay between the conditioned stimulus (CS) and unconditioned stimulus (US), according to the terminology used in classical conditioning or, more generally, in associative learning. The association between the future CS (taste stimulus) and the US (visceral malaise) can be established without temporal contingency, that is, after minutes or hours of temporal delay between the processing of both of the stimuli (Bures 1998a). This unusual property of CTA to resist long delays between stimuli is related to the physiological processes of digestion. In natural contexts, a delay always appears between the ingestion and a potential poisoning. This delay is tied up with the completion of gastric digestion processes, which result in the transport of nutrients through the gastrointestinal system and the gradual absorption of the metabolic products of digestion. Consequently, the association between taste and visceral stimuli includes this temporal requirement. As there is a

time interval between the processing of taste stimulus and the visceral disease, it is thought that CTA learning results from the association between the taste memory's trace and the gastrointestinal disease.

In nature, animals show a tendency to eat new food (which means a novel taste) with caution. This process is known as taste neophobia, and as this response limits the number of unknown foods that are ingested at a certain time, it facilitates the identification of the toxic stimulus and, therefore, the acquisition of CTA, even after long delays between the stimuli. If no aversive organic consequences follow the ingestion of novel taste stimuli, the neophobic response will be extinguished in the successive exposures, and the respective taste stimulus will be recognized as being safe. Thereby, neophobia and CTA are determining factors in the process of food selection in each animal species. As CTA gathers adaptive and evolutionary processes of learning, memory, attention, and motivation, basic research has established a study paradigm of CTA that continues to be used since its first description in the middle of the last century (Bernstein 1999; Bures 1998a).

## CTA Paradigm in Animal Research

CTA, neophobia, and other complex phenomena of learning related to taste aversion, as latent inhibition of CTA (a reduced conditioned aversion resulting from taste preexposures followed by non-aversive consequences), are being studied extensively in laboratory animals to explore the behavioral and neurobiological bases of aversive learning and taste memory (Molero-Chamizo 2015; Molero-Chamizo and Morón 2015). For example, the role of the contextual cues in the acquisition of taste aversion and latent inhibition of taste aversion has been explored by using the CTA paradigm. These studies have revealed that not only external or physical cues but also internal cues, such as the time of day, can modulate the magnitude of a taste aversion (Molero-Chamizo 2013, 2017a, 2018; Molero-Chamizo and Rivera-Urbina 2017a).

The experimental procedure used in the laboratory to induce CTA is a robust and simple tool to study the behavioral and biological mechanisms of learning and memory, in general, and taste aversion, in particular (Bures 1998a). The laboratory procedure includes ad libitum food throughout the entire procedure and a water deprivation stage in which the animals have limited access to a daily amount of water or their access to water is limited to a restricted time period each day (which is usually about 15 min). The aim of this stage is to stabilize the daily amount of water consumed by animals to obtain a baseline period. Once the initial consumptions are equated, the animals are exposed to a novel taste stimulus (representing the CS) during the next stage (the conditioning session). The taste stimulus is usually provided as fluid to facilitate the measurement of consumption. A sodium saccharin solution (0.1%) or a sodium chloride solution dissolved in water (saline 1%) are some of the taste stimuli used at this stage of the CTA paradigm. Approximately 20 or 30 min after the consumption of the new taste stimulus, a gastrointestinal distress (representing the US) is induced, usually by an intraperitoneal injection of lithium chloride (LiCl 0.15 M, 2% of body weight), although other aversive protocols have also been described (St. John et al. 2005; Traverso et al. 2012). After conditioning, a recovery day is usually introduced before testing the acquisition of CTA. In the testing day, the magnitude of the aversion to the CS that was paired with the malaise is quantified. Different tests, for example, the one-bottle test or two-bottle test, are used to quantify the strength of the taste aversion. The two-bottle test is sensitive to detect minimal aversion because animals can choose between the consumption of the taste stimulus (i.e., the CS) and water. In the one-bottle test, the animals usually ingest some amount of the CS, as it is the only consumption option presented. Thus, the amount ingested indicates the magnitude of the acquired taste aversion. As mentioned above, the reduction in the consumption of the CS after CTA learning not only indicates a conditioned avoidance response but also involves an alteration in the incentive value of the taste stimulus. As this procedure of inducing taste aversion can be easily

reproduced in the laboratory, the CTA paradigm described here is widely used in animal research. Figure 1 depicts the different stages of the CTA paradigm.

## Neurobiology of Taste Aversion

The acquisition of taste aversion and taste memory processes involve a complex neurobiological mechanism that includes different brain structures and neural pathways (Yamamoto 1993; Yamamoto and Ueki 2011). Animal model research has provided relevant information about the general mechanisms of taste aversion. However, the specific role of each structure and the connectivity of each part of the system have not been completely elucidated. The molecular mechanisms involved in taste aversion learning and memory are also an essential component of the neurobiology of taste aversion that is currently under intense research. The critical components of the neural mechanism of CTA and taste memory, as well as the related molecular pathways, will be described in this section.

Taste signals that trigger the swallowing of food start in the cells of the oral cavity membranes. These signals are projected by the VII, IX, and X cranial nerves to different nuclei of the brainstem. The first brainstem nucleus that receives the taste information is the nucleus of the solitary tract (NTS) (Harrer and Travers 1996; Spray and Bernstein 2004). Then, the taste pathway projects ipsilaterally to another brainstem nucleus, the posteromedial parabrachial nucleus (Dayawansa et al. 2014). Taste signals are then sent in an ascending direction to the following brain structures: the lateral hypothalamus, the bed nucleus of the stria terminalis, the amygdala, and the thalamus (Bielavska and Roldan 1996). The final processing reaches the gustatory insular cortex (Scott 2011; Stehberg et al. 2011). These pathways, and those involved in the processing of visceral malaise, are necessary for taste aversion learning and memory. In addition, some studies have suggested the involvement of other brain structures, such as the medial prefrontal cortex and the nucleus

**Taste Aversions, Fig. 1** Stages of the CTA paradigm used in rodents and other laboratory animals

**Taste Aversions, Fig. 2** Cortical, subcortical, and brainstem levels of taste aversion learning and memory. Arrows indicate the ascending taste pathway from the oral

cavity and the afferent (input) and efferent (output) projections described in CTA. The cranial nerves that send taste information from the oral membranes are also shown

accumbens (Marotta et al. 2014), in the acquisition of CTA. Figure 2 shows the cortical, subcortical, and brainstem components of taste aversion learning and memory.

The neural mechanism of taste aversion learning and memory includes the activity of the abovementioned structures and pathways. Less is known about the precise role of each

component of the system or the functionality of the different pathways involved. The critical function of the gustatory insular cortex and parabrachial nucleus on CTA is well established, but there is less evidence about the other brain structures. In particular, the specific role of the amygdala in the acquisition of taste aversion is one of the relevant mechanisms of CTA that need to be elucidated (Molero-Chamizo et al. 2015; Reilly and Bornova 2005; Schafe and Bernstein 1996). Some studies have tried to identify the specific nucleus of the amygdala related to the acquisition of CTA (St. Andre and Reilly 2007). The lesion studies in animal models have pointed to two amygdaloid nuclei: the central and the basolateral amygdala (Yamamoto et al. 1997). However, recent studies suggest that the main nucleus of the amygdala involved in the learning of proper taste aversions is the basolateral complex of the amygdala (Molero-Chamizo 2017b; Molero-Chamizo and Rivera-Urbina 2017b). New studies are necessary to explore the anatomical organization and the exact neurobiological mechanisms of taste aversion learning and memory.

The molecular mechanisms that trigger the acquisition and memory of taste aversion are also being intensively investigated by using animal models and in vitro procedures. These mechanisms include gene expression, receptor activity, intracellular and extracellular signaling processes, etc. Thus, taste learning and taste memory consolidation depends on protein synthesis in the gustatory insular cortex (Levitan et al. 2016; Merhav and Rosenblum 2008; Rosenblum et al. 1993). In addition, gene expression of brain-derived neurotrophic factor (BDNF) in the gustatory insular cortex and basolateral amygdala is related to the long-term synaptic plasticity processes occurring during CTA memory (Rivera-Olvera et al. 2016). With respect to receptors, the acquisition of CTA and taste memory seems to involve numerous neurotransmitter receptors, such as the  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate, the N-methyl-D-aspartate (NMDA) glutamate, and the GABA-A receptors, as well as the muscarinic receptor of acetylcholine (mACh) (Bermúdez-Rattoni 2004, 2014;

Bermúdez-Rattoni et al. 2004). Other molecules involved in cell signaling during CTA and taste learning and memory are the calcium calmodulin-dependent protein kinase II $\alpha$  (CaMKII $\alpha$ ), protein kinase A (PKA) and C (PKC), cyclic adenosine monophosphate (cAMP), and adenylyl cyclase (for a review see Molero-Chamizo and Rivera-Urbina 2017c). Although these molecules and mechanisms are beginning to be deciphered, a solid knowledge of the molecular pathways is critical to fully understand the neurobiological systems of taste aversion.

## Conclusions

The acquisition and memory of taste aversion is an adaptive learning that prevents harmful consequences of toxic food on health. This peculiar learning is easily reproduced in the laboratory, and it is a useful tool to study the behavioral and neurobiological bases of learning and memory, in general, and the complex mechanisms involved in the formation and extinction of CTA, in particular. In addition to the lesion methods used in animal research to explore the neurobiology of taste aversion, new studies are being carried out by using advanced techniques, such as immunohistochemistry, genetic engineering, molecular procedures, brain images, etc. The results of these studies might shed light on the complex taste aversion learning and memory mechanisms.

## Definition

Taxa, the plural form of taxon, are the names given to taxonomic groups in an academic system of nomenclature.

The term taxon was coined by German biologist, Adolf Meyer-Abich, in 1926 as a derivative of the word taxonomy. Taxa are used within the field of taxonomy, which is the branch of science involving the classification of organisms. Taxonomists (i.e., biologists that group organisms into categories) use taxa to organize one or more populations of a particular organism that tend to exhibit morphological, behavioral, genetic, or evolutionary similarities. Taxonomists typically assign particular taxa a name and rank, which refers to a taxonomic categorization in which organisms are organized by their relative level to other organisms. At any rank, a taxon should indicate a common evolutionary background, suggesting that all members within the same taxonomic grouping evolved from common ancestors (de Queiroz and Gauthier 1990).

The process of assigning groups of organisms with a universal taxonomic name is important to biologists, because it provides a level of academic consistency globally. Classification takes into account a variety of characteristics that are shared among a group of organisms and unlike characteristics in other groups. Historically, classification has been based primarily on morphological and genetic traits in order to put alike groups into similar categories (Hagen 2012). In the 1900s, biologists began to place groups into categories based on evolutionary processes and behavioral similarities. Examples of behavioral attributes used when assigning categories to organisms would be nesting, social behavior, antipredator responses, and feeding behaviors (de Queiroz and Wimberger 1993).

Taxa can be grouped together using a few different systems to apply a rank to an organism. Through the use of cladistics as well as phylogeny, biologists are able to understand the resemblance between genetic, evolutionary, and behavioral traits shared by organisms. Cladistics is the term used for a concept of biological classification in which groups of organisms are structured by common recent ancestors in order to form a taxonomic tree. Biologists tend to suggest common ancestral lineages when similar evolutionary traits of animals form apparent groupings that are similar in one or more characteristics. Phylogeny is much like cladistics in that organisms are grouped together on the basis of evolutionary

ancestral lineages. The difference is that phylogeny uses phylogenetic trees tend to apply a representation of the time span taken for these evolutionary changes.

Even though morphological and behavioral characteristics prove to be just as accurate as other means of taxonomic classification, phylogeny estimation, or assigning taxonomic ranking, is mostly done by biologists using morphological characteristics of an organism. Since behavioral data proves difficult to collect and categorize, morphological and genetic classification will likely maintain a larger role in taxonomic ranking systems in the future. There is presently much debate amongst the scientific community regarding the potential plasticity and/or degradation of behavioral characteristics through evolutionary processes – thus insinuating that phylogenetic classification of an organism based on behavior may not be stable enough to appropriately classify groups of organisms (de Queiroz and Wimberger 1993). Nearly the same problems using genetic sequences to classify organisms have come to light. It was found that classical morphological assessments, when compared, were very different from newer genetically derived organismal relationships. Some researchers believe that the same could be said for morphological characteristics, but currently, assigning a taxonomic rank based on morphological characteristics alongside behavioral characteristics proves to be the most representative of an organism's evolutionary lineage.

## Teaching

Laurel Fogarty  
University College London, London, UK

## Definitions of Teaching

Animal teaching has long been a contentious concept. For many anthropologists and some psychologists, teaching is necessarily a human endeavor that relies on uniquely human cognitive capabilities. However, many animal behavior

researchers use functional definitions of teaching to explore the possibility that nonhuman animals can spread useful information through teaching (see Hoppitt et al. 2008; Kline 2015 for reviews and discussion). The most commonly used operational definitions are variants of that proposed by Caro and Hauser (1992) and state that teaching occurs when a role model changes their behavior in the presence of a naïve pupil, the role model suffers a cost for this change in behavior (or does not immediately benefit from it), and the pupil learns information more rapidly than they otherwise would or learns information that they otherwise would not learn. Such definitions of teaching allow researchers to investigate putative instances of animal teaching without relying on an understanding of an individual animal's intentions, in other words, without recourse to difficult-to-prove explanations involving theory of mind. Such definitions stand in opposition to anthropocentric definitions of teaching that insist that a teacher recognizes ignorance in their pupil and intentionally seeks to correct this (Thornton and McAuliffe 2006).

While immeasurably useful to those interested in animal teaching, these functional definitions also face considerable challenges. A particular sticking point is the requirement that learning on the part of the pupil must be shown to be improved by the actions of a teacher. This can be difficult or even impossible to show conclusively without experimental manipulation of the study species, and while such manipulation is possible in some contexts (e.g., in the case of meerkats (Thornton and McAuliffe 2006, see below)), it is considerably more challenging in the case of large mammals and protected species in the wild with whom it may be unethical and impractical to experiment in such a way. Therefore, it has been argued that the definition itself makes demonstrating the existence of teaching in some animal species more difficult than others and risks excluding some interesting and important instances of non-human teaching (Hoppitt et al. 2008; Byrne and Rapaport 2011).

A number of solutions to these issues have been proposed. For example, Thornton and Raihani (2008) suggested that it might be possible

to find a correlation between the extent of exposure to teaching behavior and the skill of a pupil's performance, thus showing that teaching had acted to improve skill or knowledge. However, in response, Byrne and Rapaport (2011) point out that such approaches could also generate false negatives. For example, in a case where teachers increase or decrease teaching effort in response to individual variation in learning ability, such a correlation would not be found despite the presence of quite sophisticated teaching behaviors.

Other approaches to conclusively showing the existence of teaching using a functional definition are examined in detail by Thornton and Raihani (2010) and include the use of longitudinal studies of pupil behavior and skill as well as advocating statistical methods that can control for confounding factors such as age and learning ability. It may be the case that in order to investigate teaching in a meaningful way, the core aspects of a functional definition must remain intact. However, as pointed out by Byrne and Rapaport (2011), we may have little to lose by allowing a relaxed definition of teaching to generate putative examples of teaching in the wild – examples for which closer examination of the context and psychological underpinnings of the behavior might confirm or deny the existence of teaching. In other words, it is important that the shortcomings in a functional definition of teaching that exclude very probable cases of teaching in wild animals are carefully considered in every case.

## Examples of Animal Teaching

There are a number of putative and confirmed examples of teaching in nonhuman animal species including in domestic cats (Caro 1980a, b), monkeys (e.g., Ruiz-miranda et al. 1999; Rapaport and Ruiz-miranda 2002), some insect species (e.g., von Frisch 1967; Riley et al. 2005; Richardson et al. 2007; Franks and Richardson 2006), some bird species (e.g., Raihani and Ridley 2008), and more recently in chimpanzees (Musgrave et al. 2016). Here, it is useful to examine the evidence for teaching in some of the most widely cited examples that meet the criteria set out by Caro

and Hauser (1992) and to point to resources containing further information about others.

### **Tandem Running in Ants (*Temnothorax albipennis*)**

Ants of the species *Temnothorax albipennis* frequently lead one another from a nest to the site of a food source using what is known as “tandem running.” Here, the leading ant runs in front of a naïve individual guiding that individual to a food source or alternative nest site. While tandem running a leading ant will pause, wait for their follower, and only continue to run when tapped by the “pupil” on the abdomen thus maintaining close contact between pupil and teacher. This is clear modification of behavior on the part of the leading ant that occurs only in the presence of a naïve follower (Franks and Richardson 2006). Franks and Richardson (2006) also showed that the leading ant could “proceed four times faster from the nest to the food when not encumbered by a follower.” In other words, the leading ant suffers a considerable time cost in showing the following ant where to go, and waiting for the follower to identify landmarks and learn the route. Finally, the following ant was shown to reach food significantly faster when taught by a leader than when allowed to forage alone. This shows that the follower does, indeed, learn the location of the food or nest more quickly than they otherwise would.

An interesting aspect of the teaching identified in tandem running ants is the importance of “feedback and evaluation” between pupil and teacher, which some authors maintain is a crucial aspect of teaching (see Richardson et al. 2007, and citations therein). Such “bidirectional feedback” between the leader and follower was shown between ants during a tandem run. Not only did the follower indicate when they were ready to proceed by tapping the leader’s abdomen, but the leader was observed to slow down (and the follower speed up) when the gap between the leader and follower became large. Leader ants were also shown to evaluate the value of the goal, the speed of a tandem run, and the length of time already invested in a run when waiting for a follower to re-establish a lost contact. The example of tandem running in ants demonstrated that teaching need

not rest on the kinds of complex cognitive mechanisms usually only observed in mammals.

### **Pup Provisioning in Meerkats (*Suricata suricatta*)**

Again, using the functional definition discussed above (Caro and Hauser 1992), Thornton and McAuliffe (2006) investigated a putative example of teaching in wild meerkats (*Suricata suricatta*), which they describe as “a species living in demanding environments where food acquisition involves considerable skill.” Meerkats live in cooperatively breeding social groups of between 2 and 40 individuals and young meerkat pups are largely unable to hunt for their own prey before the age of around 90 days. Prior to that age, pups are provisioned by older individuals. Meerkats eat a number of invertebrate species, among them species of scorpion that could pose considerable risk to inexperienced pups that may be unable to disable or avoid a scorpion’s sting.

Older individuals who provision pups with food (helpers) were shown to kill or disable prey before presentation to the pups. Furthermore, helpers were shown to adjust the frequency with which they kill or disable mobile prey according to pup age, gradually introducing pups to live prey. This change in behavior was conclusively shown to be mediated by pups’ age-specific begging calls using playback experiments that showed meerkat helpers providing more disabled or dead scorpions in response to begging calls recorded from younger pups. Additional help offered to pups (e.g., a helper monitoring the pup with a dangerous food item, or directing their attention towards an ignored food item) is also important in determining whether the “teacher” in this case incurs a cost associated with their changed behavior around young pups.

Helpers appear to facilitate pup learning by creating opportunities for pups to handle live prey in a relatively safe context. In this way, young meerkats can become proficient at dealing with dangerous prey such as scorpions. Thus, Thornton and McAuliffe (2006) showed that the meerkat teachers alter their behavior in the presence of a naïve conspecific and that this is a time consuming (in other words, costly) practice. The

definition of teaching proposed by Caro and Hauser (1992) also requires that the pups learn more quickly than they otherwise would or that they learn information that they otherwise would not learn. In order to demonstrate this learning (and to head off the criticism that improvements in meerkat pup food-handling is a result of maturation, not learning), Thornton and McAuliffe provisioned meerkat pups with live scorpions or boiled egg. Those provided with the opportunity to safely manipulate scorpions were capable of dealing with complex prey when tested where those provisioned with bioled egg were not.

These experiments along with behavioral observations showed that meerkat helpers changed their behavior in the presence of young pups, providing them with a vital opportunity to learn to deal with dangerous prey in a way that would otherwise be difficult, dangerous, or impossible.

#### **Purr Calling in Pied Babblers (*Turdoides bicolor*)**

Another example of teaching according to the functional definition occurs in pied babblers. These birds teach their young to associate a specific purr call with the presence of food at the nest. This call is then used to lead young birds towards food sources or away from danger (Raihani and Ridley 2008). Raihani and Ridley (2008) showed that adult birds did not use the purr call when young birds were not present and so the behavior constituted a modification of their usual vocalizations in the presence of naïve birds. The use of purr calls also increased as the nestlings aged towards fledging. Prolonged use of purr calls was associated with slower weight gain in adult birds, showing that there are some energetic costs to making the vocalizations for the adult birds.

Finally, Raihani and Ridley (2008) showed, using playback experiments, that pairing purr calls with food delivery each time the adults approached the nest to feed the nestlings elicited earlier nestling responses to purr calls than that elicited without playback.

The example of pied babblers underlined the fact that teaching in nonhuman animals takes a

variety of forms and can fall into a number of categories. Some attempts have been made to define such categories and to link instances of nonhuman teaching to the broader social learning literature and to the broader literature on the psychology of teaching in both humans and nonhumans.

### **Categorizations of Teaching**

The examples cited above are instructive. Caro and Hauser (1992) proposed that teaching in nonhuman animals could be split into two broad categories: “opportunity teaching” defined as a “teacher putting pupil in a situation conducive to learning a new skill or acquiring knowledge,” and “coaching” defined as a “teacher changing the behavior of a pupil by encouragement or punishment.” While the examples of food provisioning in meerkats and tandem running in ants fall into the former category, the teaching seen in pied babblers falls into the latter (Raihani and Ridley 2008). These categorizations can be helpful in identifying instances of teaching in different contexts and in linking instances of teaching to the broader social learning and teaching literature. A more comprehensive categorization was devised by Hoppitt et al. (2008) who aimed to link teaching with underlying social learning mechanisms.

Taking a broad view of teaching and drawing on many confirmed and putative examples, Hoppitt et al. (2008) extended the categorizations of Caro and Hauser (1992) and showed that different social learning mechanisms could underpin teaching in different contexts. For example, they showed that teaching could rely on opportunity providing and coaching (as shown above), as well as local enhancement, observational conditioning, and imitation (all well-studied social learning mechanisms).

In 2015, Kline added to the growing literature on teaching by proposing further categorizations and examining the links between disparate schools of thought on teaching; both human and nonhuman. The framework proposed by Kline aimed to provide a means to examine nonhuman

animal teaching and to explore the uniquely powerful teaching abilities seen in humans.

## Conclusions

The study of animal teaching is controversial but continues to move forward as more putative examples of teaching emerge. Teaching appears to be difficult to observe in the wild, especially relative to other forms of social learning, which are often observed across a huge range of species. There are a number of plausible reasons for the seeming rarity of teaching in nature. First, teaching may be rarely observed because the act of teaching itself is rare in certain contexts (Byrne and Rapaport 2011); second the definitions we use may be restrictive and cause frequent false negatives (Caro and Hauser 1992); or third the selective pressures involved in the evolution of teaching may mean that it is, indeed, rare in nature (Fogarty et al. 2011). Further studies of teaching across species, further refinements of our definitions, as well as innovative experimental and statistical approaches are crucial to drive the study of nonhuman animal teaching forward and, eventually, to link this field with the considerable literature on the most sophisticated example of animal teaching: that of humans.

## Technical Intelligence Hypothesis

Camilla Cenni and Jean-Baptiste Leca  
Department of Psychology, University of  
Lethbridge, Lethbridge, AB, Canada

### Synonyms

Extractive foraging hypothesis; “Technological intelligence” hypothesis

### Definition

The “technical intelligence” hypothesis is an evolutionary approach proposing that material innovations and object-oriented behavioral skills (e.g., caching and recovering nonperishable food, detecting and extracting encased food, making and using tools, building shelters) constitute major driving forces in increased relative brain size and intelligence across various animal taxa, through the selection of cognitive features that sustain complex and flexible technical proficiency (Byrne 1997).

### Introduction

Why do some animal species have large brains relative to their body size, even though the growth and maintenance of this special organ is associated with significant energetic costs and developmental constraints that jeopardize survival and delay reproduction? There are two main evolutionary hypotheses to explain the emergence of bigger brains and more sophisticated cognitive abilities in humans and nonhuman animals (and particularly nonhuman primates): the “social intelligence” hypothesis (SIH) and the “ecological intelligence” hypothesis (EIH). For both the SIH and EIH, the ultimate drivers of brain evolution are grounded in ecological factors that are essential for survival and reproduction (i.e., finding food and avoiding predators). However, the key

difference between these two evolutionary approaches lies in *how* these fundamental ecological goals are achieved. Proponents of the SIH contend that the solutions to these ecological problems belong to the socio-cognitive domain, whereas advocates of the EIH argue that these solutions are found in physico-cognitive abilities (Tomasello and Call 1997).

The rationale of the SIH is as follows: confronted with the two major ecological challenges of finding food and avoiding predators, some animals have evolved two types of social solutions, respectively socially mediated learning of foraging skills (i.e., learning from more experienced group members) and forming stable social groups of bonded individuals who have a greater chance to detect predators and protect each other reliably through cooperative behavior. However, living in large and complex groups led to secondary social challenges associated with interindividual competition for physical, social, and sexual resources (i.e., food, shelters, grooming partners, allies, and mates). Such challenges selected for socio-cognitive abilities pertaining to social representation and social memory (i.e., keeping track of one’s and others’ social relationships including dominance, kinship, and affiliation), social strategizing or Machiavellian skills (e.g., cooperating, forming alliances, predicting others’ behaviors and intentions, manipulating/deceiving others), and complex communication skills (e.g., representational, semantic, and arbitrary vocal repertoire, language; Dunbar 1998).

The EIH focuses on two main dietary characteristics: frugivory and embedded foods. The ecological challenges associated with frugivory are due to the fact that fruits vary in space (i.e., they are patchily distributed), time (i.e., they are seasonally available), ripeness, nutritional contents, and toxicity. The corresponding cognitive demands include remembering fruiting locations, predicting fruiting timing, assessing the costs and benefits of eating novel fruits, and identifying their toxic parts. Such challenges selected for physico-cognitive abilities pertaining to mental maps to represent space, time, and quantity-based decision-making, as well as associative

learning of food choice. The ecological challenges associated with embedded foods are due to the fact that some high-quality food items are hidden inside tough protective matrices (e.g., protein-rich seeds encased in hard shells) or difficult-to-process foraging substrates (e.g., lipid-rich insect larvae enclosed within bamboo stalks). The corresponding cognitive demands include detecting the presence of these concealed foods, assessing objects' affordances, and food-processing/extracting, sometimes by making and/or using tools. These mental abilities are supported by extractive foraging actions that should be fine-tuned, coordinated, and sequential. Such challenges selected for physico-cognitive abilities pertaining to sensorimotor coordination, complex action planning, and learning about the causal structure of the physical environment and the physical consequences of one's actions. The latter set of extractive foraging-related cognitive skills associated with embedded foods is referred to as "sensorimotor intelligence" or "technical intelligence" (Byrne 1997; Parker and Gibson 1977; Rosati 2017).

The "technical intelligence" hypothesis is thus a subcategory of the EIH. It aims to provide a mechanistic and functional explanation for the evolution of intelligence in humans and non-human animals. Technical innovations based on the ability to combine and use inanimate objects sequentially and instrumentally to solve a variety of problems in the physical domain may have created higher cognitive demands that favored an increase in the encephalization quotient (i.e., brain-to-body weight ratio after controlling for allometric effects as well as the size and organization of specific brain components (e.g., neocortex) which are broadly considered neural proxies for intelligence; Byrne 1997). Cross-species comparative analyses showed a strong positive correlation between relative brain size of birds and primates and their ability to use different objects in novel, instrumental, and flexible ways (Overington et al. 2009; Reader and Laland 2002). More encephalized primate species (i.e., those with a bigger "executive brain," including larger neocortex and striatum) exhibited more tool use in a foraging context than less encephalized

ones (Lefebvre 2012). In primates, nontechnical innovations also show positive correlations with relative and absolute brain size, but those relationships are not direct; they are mediated by additional factors, such as social learning, diet, and life-history variables (Navarrete et al. 2016). For instance, dietary generalism (i.e., a broad selectivity for different food resources) predicted enhanced encephalization, suggesting that the ability to exploit novel food sources may have led to an increase in brain size.

In cognitive tasks testing for physical cognition, causal reasoning, working memory, and self-control, tool-using bird species generally outperform closely related non-tool-using species, with some exceptions (Teschke et al. 2013). Advanced forms of sensorimotor intelligence have also been found in non-tool-using animal species that show flexible extractive foraging techniques (e.g., keas, a New Zealand parrot species, exhibit outstanding performance in several physico-cognitive tasks, suggesting good understanding of the physical properties of objects; Huber and Gajdon 2006). Indeed, it is not the *fact* that animals use tools, but the *way* they use it (i.e., in a hierarchically organized sequence of actions) that may shed light on the sophisticated cognitive abilities underlying complex extractive foraging strategies (Byrne 1997).

## Factors Responsible for the Emergence of Technical Innovations

### Extrinsic Factors

To explain the distribution of material innovations that might have driven the emergence of enhanced cognitive abilities, the "technical intelligence" hypothesis considers a combination of external and internal factors. Exploring the role of extrinsic factors allows us to integrate and refine the "extractive foraging" hypothesis (Parker and Gibson 1977), which focuses on gaining access to embedded foods. Both the *necessity* to exploit novel, energy-rich, and encased food sources (e.g., in periods of food scarcity), and the *opportunity* to express new extractive foraging techniques (e.g., given the presence of instrumentally

relevant objects or food sources that can be exploited) are favorable conditions for technical innovations to emerge. However, ecological factors alone only partially explain the limited distribution of tool use among extractive foragers (e.g., Koops et al. 2015a). Even though chimpanzees and bonobos live in similar ecological conditions, they considerably differ in their rates and forms of instrumental object manipulation in the wild, with tool use being virtually absent in bonobos, whereas chimpanzees are the most frequent, versatile, and proficient tool users besides humans.

For years, the “technical intelligence” hypothesis has been seen as an alternative to the SIH, according to which the major drive for the evolution of intelligence may be found in the complexity of species’ social systems (Dunbar 1998). However, as indicated before, these two hypotheses are not mutually exclusive, and such a dichotomous view has recently been reconsidered (Parker 2015). In its revised version, the “technical intelligence” hypothesis integrates social influences as fundamental in the expression of material innovations. In a systematic cross-species comparative review, the rates of tool use, innovation, and social learning in primates covary and are all positively correlated with enlarged brains (Reader and Laland 2002). Indeed, although most object-oriented behaviors are performed solitarily, they often occur within a social environment, and social influences affect the *acquisition* and *maintenance* of such technical innovations.

First, social influences mediate the *acquisition* of different instrumental behaviors, by providing means of transmission from older kin individuals (i.e., vertical transmission) or from peers (i.e., horizontal transmission). For example, the population of chimpanzees living in the Goualougo Triangle, in the Republic of Congo, is characterized by a relatively complex tool-use repertoire, together with higher levels of social tolerance and spatiotemporal coordination than other populations of chimpanzees, including numerous instances of coaction (i.e., when the demonstrator of a tool use action allows an observer to touch its hand or tool; Sanz and Morgan 2013).

Second, social cues favor the *maintenance* of technical innovations through direct and indirect

influences. Increased social tolerance allows unskilled group members to get exposed to the demonstration of novel foraging techniques by proficient group members (i.e., direct learning via emulation, imitation, and possibly teaching; Boesch et al. 2019) or to the informative presence of half-processed food parts and tool-using ateliers left behind by skilled foragers (i.e., indirect learning via stimulus enhancement; Gunst et al. 2010; Inoue-Nakamura and Matsuzawa 1997). In tool-using primate species, such as capuchins and chimpanzees, encountering previously manipulated foraging artifacts enhances the physical affordances of objects (i.e., their perceived opportunities for action) and the subsequent expression of instrumental object manipulation (Fragaszy et al. 2013). Even the noninstrumental manipulation of objects, such as the culturally maintained stone-directed play behavior performed by Japanese macaques, can be socially influenced, both directly (i.e., through the observation by naïve infants of their mothers as stone play demonstrators; Nahallage and Huffman 2007) and indirectly (i.e., through the stimulating effect of stone play artifacts, such as piles of stones left on the ground by previous stone players; Leca et al. 2010).

### Intrinsic Factors

Given that extrinsic factors are not sufficient to fully explain the phylogenetic distribution of technical innovations, the “technical intelligence” hypothesis also points at specific intrinsic factors, such as anatomical features (e.g., dexterous body parts, like hands and beaks) and psychological predispositions (e.g., motivation to manipulate objects), as key evolutionary drivers of the emergence of material innovations. It is not surprising that the highest rates of technical innovations are found in primates, and more specifically in humans, followed by great apes, whose hands possess the greatest potential for movement *complexity* and *dexterity*, as measured by the diversity of gripping and grasping capabilities. In a comparative study of 36 nonhuman primate species, unimanual/bimanual actions, synchronous/asynchronous use of hands and fingers predicted the occurrence of different categories of object manipulation, with species having a greater

manual dexterity being able to perform more complex types of object manipulation (Heldstab et al. 2016). However, hands are not necessary for technical innovations; in birds, morphological characteristics of the beak (e.g., depth, shape) play a major role in the manipulative complexity of tool-using corvids (e.g., New Caledonian crows, Goffin's cockatoos, keas; Huber and Gajdon 2006; Kenward et al. 2011).

From both proximate and ultimate perspectives, innovative instrumental object manipulation and tool use can stem from, or at least be facilitated by, the expression and transformation of noninstrumental object-directed behavior patterns, such as object play. In a wide range of animal taxa, functional/"serious" technical innovations (e.g., tool use) and purposeless/"playful" object-oriented actions covary in frequency and share broad structural similarities. For example, object play behavior patterns and tool use actions are significantly more frequent, diverse, and complex in chimpanzees than in their sister species, bonobos, even in their similar natural habitats (Koops et al. 2015a, b). Likewise, within the corvid taxon, there is a high degree of cross-species covariation between material neophilia (i.e., object-directed explorative tendencies and the propensity to engage in versatile and complex object play) and physico-cognitive abilities (i.e., mechanical problem-solving strategies, extractive foraging techniques, and tool use proficiency; Huber and Gajdon 2006). However, the nature of the developmental and evolutionary links between various object-directed activities is far from being unraveled, and the question of whether (and if so, to what extent) noninstrumental object manipulation facilitates the expression of instrumental object manipulation, and thus technical intelligence, is still open.

### **How Does the "Technical Intelligence" Hypothesis Explain the Role of Object Play in the Emergence of Technical Innovations?**

On the one hand, object play behavior may have driven the selection for the functional

manipulation of objects by providing preexisting schemata transferable to instrumental contexts (Parker and Gibson 1977). Noninstrumental exposure and handling experience with objects provide opportunities to learn about the properties and affordances of these objects, and help refine sensorimotor coordination, through the acquisition and practice of manipulative dexterity (Lockman 2000). In the Sonso chimpanzee community in Uganda, low interest in, and limited spontaneous manipulation of, sticks may explain the lack of stick-assisted tool use; individuals preferentially explored other objects that were later used as tools (Lamon et al. 2018). Similarly (Kenward et al. 2011) compared the development of noninstrumental object manipulation (i.e., object handling that is not immediately functional) in New Caledonian crows, a tool-using species, and in common ravens, a species that does not seem to use tools in the wild. They found no significant difference in the rates of noncombinatorial object manipulation, which probably results from a general/inherited manipulative tendency in all corvids. However, plastic object-directed playful sequences involving object combinations (e.g., object positioning, inserting, or rubbing in relation to other objects or a substrate) that are considered behavioral precursors of later functional manipulation (e.g., tool use) became significantly more frequent in New Caledonian crows than in common ravens during critical stages of development.

On the other hand, the intrinsic propensity to manipulate objects could facilitate the emergence of technical innovations by maintaining high levels of material neophilia (e.g., sustained interest in, and attention to, objects). Intrinsic motivation for object manipulation may promote the integration and functional use of objects in various behavioral technical domains. In primates, tool use acquisition is a lengthy process, in which learners start reaping extrinsic rewards for their actions after years of unsuccessful practice (e.g., stone tool-assisted nut-cracking behavior in chimpanzees and capuchin monkeys; Frigaszy et al. 2013; Lonsdorf 2006). In the meantime, the intrinsically rewarding nature of non-instrumental object manipulation, including

object play, characteristic of immature individuals, may serve the function of maintaining high levels of motivations in unskilled learners. For example, the playful manipulation of lithic material by juvenile monkeys precedes the acquisition of stone tool-assisted shellfish foraging in a free-ranging and coastal population of Burmese long-tailed macaques in Thailand (Tan 2017).

As opposed to instrumental object manipulation (e.g., tool use) which is *product-oriented*, object play is a *process-oriented* activity during which the performer acquires information about an action or an object involved in that action. It is acknowledged that problem-solving performance depends on an individual's motivational state, with low levels of extrinsic motivation being generally associated with poor performance. However, high levels of extrinsic motivation may also reduce an individual's technical performance, by narrowing its attention towards the product, target, or goal, rather than the process to achieve them. A comparative experimental study in great apes showed that learning about action–outcome contingencies preferentially happened during free exploration, whereas the presence of a food reward during the baited-condition distracted the subjects and delayed the acquisition of the solution to the problem (Ebel and Call 2018).

Although object play is generally a solitary activity, some species integrate specific objects into social play interactions, which may enhance interest in these objects and provide an opportunity to understand how they may be used in a social context. In Japanese macaques, branches are often incorporated in social play bouts in which the protagonists engage in role turn-taking (i.e., object holder versus non-object chaser; Shimada 2006). In some groups of the same species, unaimed stone-throwing is considered a form of tool use that serves the function of increasing the effect of agonistic displays during periods of disturbance (Leca et al. 2008).

The proximate and ultimate links among different object-oriented activities and technical innovations remain unclear. The relationships between playful and functional object manipulation have been extensively explored in captive settings but not in the wild (i.e., considering

ecologically and socially relevant scenarios, as required by the “technical intelligence” hypothesis). Through a cross-species comparative approach, the “technical intelligence” hypothesis may be used to generate testable predictions about the developmental and evolutionary connections between noninstrumental and instrumental object manipulation.

## Conclusion

Even though the SIH has been the predominant explanation for the evolution of primate cognition, the EIH is being revived, and particularly through the “technical intelligence” hypothesis (Rosati 2017). This hypothesis explores the role of ecological and social factors, together with internal predisposition to manipulate objects, in the emergence of material innovations. Still, the relative contributions of each of these factors remain unclear. Overall, EIH and SIH are not mutually exclusive; it has even been proposed that stone tool-making paved the way for the evolution of language in human ancestors, as both activities are underlain by complex, abstract, and sequential thought.

## Tecumseh Fitch

Thomas Bugnyar  
University of Vienna, Vienna, Austria

### Introduction

Tecumseh Fitch is professor and cofounder of the Department of Cognitive Biology at the University of Vienna, Austria. He studies the biology and evolution of cognition and communication in humans and other animals and in particular the evolution of speech, language, and music. He favors a broad comparative approach, studying homologous and analogous structures and processes in a wide range of species. In doing so, he builds bridges between disciplines ranging from linguistics to neuroscience.

### Fitch's Background

William Tecumseh Sherman Fitch (III) was born on May 6, 1963, in Boston. He bears the name of his great-great-great grandfather, General William Tecumseh Sherman, as did his father and grandfather before him. The name Tecumseh originated with the Shawnee chief, who teamed up with the British to fight westward expansion by American colonists.

Fitch is the first member of his family who became a scientist. Once he discovered his passion for science, he chose a PhD over an education as artist. Drawing and music (guitar, singing, composing) remain his main hobbies, which he occasionally combines with research. For instance, he enjoys graphically illustrating his publications on vocal anatomy and collaborates with professional musicians on research

questions. Fitch also enjoys running, a hobby he shares with his wife Dr. Gesche Westphal-Fitch.

### Scientific Career and Output

Fitch spent his college years in New England, receiving his BA in biology (1986) and PhD in Cognitive and Linguistic Sciences from Brown University (1994). He then worked as postdoctoral fellow at MIT and Harvard University (1996–1999) and later held a lecturer position at Harvard, first in the Department of Biology and then Psychology (1999–2002). In 2002, he moved to Europe, where he was an invited fellow at the European Institute for Advanced Studies in Berlin, Germany (2002–2003), then a senior lecturer, and finally reader at the School of Psychology, University of St Andrews, UK (2003–2009). He was Leibniz professor and visiting scholar at the Max Planck Institute for Evolutionary Anthropology in Leipzig, Germany (2006). Since 2009, he has been professor of Evolutionary Cognitive Biology in Vienna, Austria.

A key feature of Fitch's research is his cross-disciplinary approach. While his work is deeply rooted in biology, spanning from animal behavior to physiology and anatomy, he applies evolutionary thinking to various fields and disciplines outside biology (linguistics, musicology, and aesthetics). His broad interests are reflected not only in his many national and international collaborations, including researchers from natural sciences and humanities alike, but also in the formation of new research entities and interdisciplinary research foci. He is cofounder of a new department and very active in building up interfaculty and interuniversity programs that promote cognitive science and neuroscience in Vienna.

Fitch received international recognition for his studies on vocal anatomy, notably the discoveries that vocal tract length and formant frequency dispersion correlate with body size (Fitch 1997) and that a descended larynx is not a uniquely human feature (Fitch and Reby 2001). He became further renowned for his work on the evolution of language. In a seminal paper with Marc Hauser and

the famous linguist Noam Chomsky, he introduced the comparative approach to the “language faculty” (Hauser et al. 2002). In the following years, he tested and verified the hypothesized computational constraints on syntactic processing in nonhuman primates (Fitch and Hauser 2004) and other animals. Fitch still pursues both research lines – bioacoustics and bio-linguistics – today (e.g., Fitch et al. 2010, 2016; Herbst et al. 2012; Bowling and Fitch 2015). He conducts highly productive and well-funded research programs (e.g., ERC advanced grant SOMACCA, FWF doctoral programs “Cognition & Communication”), applying state-of-the-art methods for investigating sound production and perception mechanisms (noninvasive imaging techniques like X-ray and fMRI, excised larynx studies with high-speed video).

Fitch’s scientific output includes >170 research articles in peer-reviewed journals (including highly prestigious journals like *Science*, *Nature*, *Trends in Cognitive Science*, *PNAS*) in addition to several semipopular articles and book chapters. In 2010, he summarized his findings in a book entitled *The Evolution of Language*. As a gifted lecturer, Fitch is regularly invited as plenary speaker at scientific conferences as well as for public lectures, podium discussions, and television documentaries. His contribution to the field has been recognized via academic honors, like a Leibniz Professorship and Honorary Professorship at the University of St Andrews, and invitations to serve on ERC panels, editorial and advisory boards.

## Teleology Versus Teleonomy in Animal Behavior

Yzar S. Wehbe<sup>1</sup>, Patrick K. Lewtas<sup>2</sup> and Todd K. Shackelford<sup>1</sup>

<sup>1</sup>Department of Psychology, Oakland University, Rochester, MI, USA

<sup>2</sup>Department of Philosophy, American University of Beirut, Beirut, Lebanon

## History and Background

Aristotle proposed that any object or phenomenon can have four different kinds of explanations:

material, formal, efficient, and final (Aristotle, c. 350 BC/1930). In describing these four types of explanations, Aristotle used the Greek term αἴτιον (aition), which has been translated as *causes*, although the meaning is closer to *grounds for* or *reasons* (Chapman 2020). According to Aristotle, it is a combination of these “four causes” that offers a complete understanding of an object or a phenomenon. The “final” cause refers to the end, purpose, or final goal of the object or phenomenon – the final state that it moves toward (*telos*). For example, the *telos* or end of an acorn is to become a fully grown oak tree. That *telos*, the “final end state” or goal, ostensibly *explains* why the acorn came to be and why it is the way it is. Teleological explanations of nature are controversial in science, as they imply some form of backward causation, whereby a future goal or end state causes objects and phenomena in the present. If teleology in its classical sense is inseparable from these assumptions, then it is inappropriate to employ teleological explanations in biology, where backward causation has no place. However, biologists still use teleological language, and one debate is whether the use of such terminology is literal or merely figurative (e.g., Mayr 1992; Neander 1991; Wright 1976).

## Useful Distinctions

### Functional Versus Mechanistic Explanations

Both Tinbergen’s “four questions” and Mayr’s distinction between ultimate (or distal) and proximate explanations are useful for understanding teleological explanations in biology (Mayr 1961; Tinbergen 1963). Tinbergen (1968) showed that one can explain a trait by addressing four issues at parallel levels of analysis: (1) survival value (i.e., function), (2) mechanism (i.e., causation), (3) development (i.e., ontogeny), and (4) evolution (i.e., phylogeny). It is the first of Tinbergen’s questions that relates to *telos* or purpose.

Mayr defined ultimate or distal explanations as historical accounts that explain why an organism has a certain trait in terms of differential reproduction in the distant past. While there is debate about what Mayr meant by “ultimate cause,” it can

roughly be thought of as representing two of Tinbergen’s questions: function and phylogeny. Mayr’s “proximate cause,” on the other hand, can be thought of as invoking explanations that are more proximate, as in closer to the present, such as answers to Tinbergen’s questions about mechanism and development.

In the study of animal cognition and behavior, identifying the proximate and mechanistic features of a trait is important for understanding the function of the trait and vice versa. Functional hypotheses yield specific predictions about proximate and mechanistic phenomena, and an understanding of the latter can rule out certain functional hypotheses and point researchers toward others (Lewis et al. 2017).

### Teleological Versus Teleonomic Explanations

Functional explanations do not need to be teleological. This is demonstrated by evolutionary biology and the study of animal behavior, because an understanding of the process of natural selection obviates the need for a designer and also explains why traits in nature *appear* as though they were designed with a *telos* in mind even if they were not.

In the classical sense, a teleological explanation invokes an internal striving toward a *telos*, goal, or end state – an explanation that contains a whiff of the supernatural. Accordingly, explanations are truly teleological if the purported goal or function is thought to be a cause of the phenomenon despite coming *after* it in time. By contrast, functional explanations in biology refer to the evolutionary history of a species, namely, the effects of a trait on survival or reproduction in past generations. This history is antecedent to the current form of the trait. Functional explanations in biology are therefore normal instances of the past causing the present and are not teleological in the classical sense.

As Pittendrigh has stated: “It seems unfortunate that the term ‘teleology’ should be resurrected. . . . The biologists’ long-standing confusion would be more fully removed if all end-directed systems were described by some other term, like ‘teleonomic,’ in order to emphasize that the recognition and description of end-

directedness does not carry a commitment to Aristotelian teleology as an efficient causal principle” (Pittendrigh 1958, p. 394). Teleonomic explanations therefore refer to the ends or functions of traits without assuming or implying that these future ends cause the form of traits in the present. Teleonomic explanations *appear* teleological, and may even use the language of teleology, but are figurative and do not involve teleology in the sense of backward causation.

George C. Williams has suggested that the term “teleonomy” be used “to designate the study of adaptation” (1966, p. 258). Williams argued that adaptations should be identified on the basis of the precision, economy, efficiency, reliability, and complexity with which they solve their respective adaptive problems (Williams 1966). These five qualities represent the relevant evidentiary criteria for reverse-engineering the extent to which a trait shows evidence of “special design,” that is, the extent to which a trait can be considered an adaptation (Williams 1966). While these five evidentiary criteria could benefit from more concrete operationalizations, reasonable working definitions exist (Al-Shawaf et al. 2020). Comparative studies of animal behavior and morphology can also be useful when assessing whether a trait is an adaptation. For example, if different species faced similar adaptive problems during their evolution, convergent evolution may lead to similar adaptations to similar ecological problems in different species.

The key point about teleology and teleonomy is that adaptations may appear teleological, and researchers may even use teleological language to describe them. Still, the teleological language is a linguistic shorthand for a normal, quotidian causal process (i.e., a history of differential reproduction) in which the past – not the future – caused the present structure and function of the adaptation.

Goal-directed human behaviors provide an interesting special case: humans are capable of consciously representing goals that they strive toward, which may make a certain variant of teleological explanations less obviously objectionable for certain human behaviors. However, the process is still one of normal causation in which the past causes the present: humans’

conscious motivations to reach their goal cause behaviors that propel them toward their goals. There is thus no need for backward causation, a supernatural telos, or anything more exotic than ordinary causation.

## Misunderstandings Related to Teleological Explanations

Humans appear to be predisposed to think about nature using teleological language (e.g., Kelemen et al. 2013). This may impede people’s accurate (non-teleological) understanding of biological traits. Unless done carefully, the use of teleological and teleonomic explanations in biology may generate or exacerbate misunderstandings about how natural selection works (Al-Shawaf et al. 2018). These include the following two misunderstandings:

### The Progressive Evolution Misunderstanding

One misunderstanding is that evolution has a goal or direction – this idea is also known as orthogenesis or evolutionary progress. If evolutionary change was geared toward a particular goal or was directional in nature, then it might be teleological. However, the theory that evolutionary change is inherently progressive or directed toward a particular end is mistaken.

### Fitness-Maximizers Misunderstanding

A rigorous evolutionary approach to psychology and behavior should not involve a search for how traits *maximize fitness* in any teleological sense (Symons 1979). The distinction here is between two ways that biologists approach organisms: (1) as fitness-maximizers (an inappropriate approach that Tooby and Cosmides (1992) call fitness teleology) and (2) as adaptation-executors (a non-teleological approach to evolved psychology). “Fitness teleologists” may approach behavior with the following question: “How does this behavior maximize this organism’s fitness?” A fitness teleologist who assumes an animal is a fitness-maximizer may have difficulty answering questions like, “Why aren’t all men lining up at sperm banks to donate their sperm?” or “How is

this obese zoo bear increasing its fitness by eating more sugary confections?” By contrast, an adaptationist will not assume that current behavior maximizes fitness. Instead, he or she may ask why the bear’s evolved neurocognitive mechanisms sometimes cause non-adaptive behaviors. The more useful questions might be: “What is the underlying neurocognitive architecture that leads to this behavior in certain contexts?” and, as Tooby and Cosmides put it, “What are the design features of this architecture— if any—that regulate the relevant behavior in such a way that it would have constituted functional solutions to the adaptive problems that regularly occurred in the species’ evolutionary history [even if it is not adaptive in this particular instance]?” (Tooby and Cosmides 1992, p. 55). This way, rather than assuming that every biological trait or behavior contributes to the telos of fitness maximization, scientists can approach behavior by considering how past selection crafted adaptations that may or may not lead to adaptive behavior in the current instance.

## Conclusion

A teleonomic explanation is a metaphorical (and therefore legitimate) cousin of a teleological explanation of nature. Teleonomy is simply the study of evolved functions, which are key to explaining the existence and form of adaptations. Biologists frequently use teleological language such as “birds sing *in order to* attract mates” for the sake of brevity. Still, as indicated by the frequent use of scare quotes and disclaimers, biologists’ use of teleological language is figurative and “should not be taken to imply that evolution proceeds by anything other than from mutations arising by chance, with those that impart an advantage being retained by natural selection” (Maddrell 1998, p. 2461).

In sum, natural selection explains the appearance of design without the need for a designer and the appearance of teleology without the need for a supernatural telos. Teleological language (teleonomy) is perfectly acceptable if we remember that it is a linguistic shorthand and do not

make the mistake of permitting true teleological (backward) causation into our explanations.

## Temperament

Erin E. Frick  
Department of Psychology, University of  
Southern Mississippi, Hattiesburg, MS, USA

## Synonyms

Constitution; Disposition; Nature; Personality

## Introduction

The study of temperament in nonhuman animals is of great interest due to recent advances that demonstrate a relationship between temperament and animal welfare, immune functioning, social dynamics, and reproductive success (e.g., Capitanio et al. 1999; Fairbanks and Jorgensen 2011; Sih et al. 2004). In humans, temperament is defined as inherited early behavioral tendencies that are observed and continue to develop into adulthood and serve as the building blocks for personality (Gosling 2001). However, identifying what constitutes as temperament in nonhuman animals has been difficult to agree upon in the literature. The terms temperament and personality have at times been used interchangeably when describing the different behavioral responses an animal can exhibit. When expressed as separate terms, temperament tends to describe an individual's inherited genetic-based behavioral differences in a nonsocial context, whereas personality describes nongenetic

differences in behavior in social contexts (Carter et al. 2013; Clarke and Boinski 1995; Coleman 2012; Watters and Powell 2012). Thus, temperament is present during infancy, is thought to be innate, and may consist of physiological emotional and cognitive responses that are consistent over time.

There are several methods present to assess temperament in nonhuman animals. The first and simplest methodology is to study the animals in a naturalistic setting, with no manipulation of the environment. When using an experimental design, temperament is most commonly assessed by presenting a novel object or stimuli in the feeding area or environment of the animal, and observing their reaction (i.e., approach or avoidance; e.g., Capitanio 1999; Koolhaas et al. 1999). Researchers can record these responses to determine what temperament constructs are present by conducting ratings or utilizing the coding/collating of behavior methodology (Freeman et al. 2013; Freeman and Gosling 2010). Behavioral coding consists of researchers recording the type, frequency, and duration of any particular behavior and then classifying those behaviors into subsequent groups (i.e., traits) of commonly occurring patterns of behavior. Ratings consist of two or more judges scoring each animal on a number of predefined temperamental traits. These scores are then analyzed with factor analysis to reveal what dimensions of temperament may be present. Frequently reported dimensions related to temperament include proactive-reactive and bold-shy dimensions (e.g., Koolhaas et al. 1999). Previous research suggests that bold/proactive individuals are more likely to explore and interact with their environment and exhibit a lower stress response to novel stimuli. Conversely, shy/reactive individuals are more cautious when approaching novel situations, exhibit a higher stress response, and are slower to react to challenges (Koolhaas et al. 1999; Sih et al. 2004; Groothuis and Carere 2005). Recent research has shown that along these axes are other dimensions present, such as activity, fearfulness, confidence, excitability, and sociability (e.g., Budaev 1998; Capitanio 1999; Weiss et al. 2006).

## Applications of Temperament Assessments

The study of temperament in animals is relevant to many aspects of a species' life history. In domestic dogs (*Canis familiaris*), assessments of temperament are considered very important when determining the adoptability of shelter dogs into different types of family homes (i.e., dogs that get along with children or other dogs/pets, etc.). Understanding the individual temperament of each dog can help increase the likelihood of a successful adoption placement (De Palma et al. 2005). Identifying various temperament types can also aid in determining the suitability of a dog to work as a police dog, guide dog, medical dog, rescue dog, or other role where the dog performs a job or role with humans (Jones and Gosling 2005). Similarly, the animal-caretaker relationship for domestic and managed care animals can be greatly affected by an individual's temperament. Understanding of an animal's temperament can indicate which individuals will benefit from a great deal of attention from their caretakers versus individuals that require less attention to minimize anxiety or stress. For example, stump-tailed macaques (*Macaca arctoides*) were rated by animal care staff on a scale for the temperament trait friendliness, and found that the individuals with lower friendliness scores exhibited more self-directed and scratching behaviors, an indication of agitation or anxiety, when animal care staff were present (Waitt et al. 2002). Individuals with higher friendliness scores had more positive interactions with animal care staff and sought out more of this attention, possibly because the human interaction was a rewarding experience. Applications of temperament in managed care facilities can inform staff as to the best management practices to optimize an animal's welfare.

Temperament assessments have also been shown to help predict the trainability of individual animals. Shy, stress-sensitive individuals may experience some anxiety and minimal benefit from various environmental enrichment options compared to bold or exploratory individuals. Several studies have examined how an individual animal's temperament affects the effectiveness of

certain forms of enrichment. For example, Fox and Millam (2007) tested juvenile orange-winged Amazon parrots (*Amazona amazonica*) for temperament fearfulness by observing their reaction to a novel object in their feeding area. They were then exposed to two forms of enrichment: high-novelty with frequent changes in the enrichment item presented and low-novelty where the same form of enrichment was presented repeatedly. Overall the birds reacted less fearfully toward the high-novelty enrichment. However, the animals that were considered more fearful from the temperament test also exhibited apprehensive and anxious responses toward the high-novelty enrichment type. Similarly, Yamanashi and Matsuzawa (2010) examined the behavioral responses of six chimpanzees on a series of cognitive tasks. Three of the subjects were labeled stress-sensitive due to the scratching and self-directed behaviors observed when completing the cognitive tasks. These stress-sensitive subjects were more likely to become agitated when answering incorrectly compared to the stress-resistant chimpanzees, suggesting that cognitive tasks may be an enriching experience for some animals, but not all. The results from these various studies emphasize the importance of considering temperament in the effectiveness of different types of enrichment for individual animals. Understanding what will decrease stress in an animal can contribute to promoting its overall health and welfare.

The study of nonhuman animal temperament as it relates to animal welfare can provide long-term benefits to both wild and captive populations. Knowledge of temperament can help and predict outcomes to social conflict or what individuals will spend more time together. Bold individuals can help maintain social stability whereas shy individuals are more vulnerable to stressors that disrupt group dynamics (McCowan et al. 2011). In rhesus macaques (*Macaca mulatta*) successful pairings (i.e., no aggressive behaviors observed) were more likely to occur in individuals with a minimal difference between their scores for the temperament trait inhibition compared to unsuccessful pairings (McMillan et al. 2003). The authors then paired 18 sets of

similar temperament (i.e., inhibition) partners and 19 partners with different temperaments and found that more positive social behaviors were occurring between the partners that had similar scores for inhibition. Thus pairings with similar temperament exhibited more affiliative behaviors and less aggressive behaviors compared to the pairings of different temperament individuals. More recently, Weinstein and Capitanio (2008) examined how infant temperament affected later social relationships in rhesus macaques. Temperament was assessed with the Infant Biobehavioral Assessment and social behaviors were assessed at 1 year of age. The results indicated that individuals with similar temperament traits were more likely to associate and engage in positive, affiliative behaviors with one another at 1 year of age. In a follow-up study, the yearlings with similar temperament trait scores for the trait equitability were more likely to maintain their affiliative relationship at 2 years of age (Weinstein and Capitanio 2012). Overall, these various studies suggest that various temperamental factors influence partner choice for decreased aggressive interaction and increased positive social behaviors.

The study of temperament as it relates to an animal's propensity to feel anxious or fearful is one of the most commonly discussed uses of temperament analyses. The mother's milk for infant rhesus macaques is also known to affect temperamental responses related to stress, where infants that nursed from mothers with higher available milk energy (AME) exhibited higher levels of activity and exploration during novel situations compared to infants nursed with lower AME. This suggests that AME may be an important physiological cue for the development of temperament (Hinde and Capitanio 2010). For example, when looking at the relationship between temperament and stress response in infant rhesus macaques, highly reactive individuals exhibit greater hypothalamic pituitary adrenal (HPA) activation and stress-behavioral responses to novel stimuli compared to less reactive individuals (Suomi 1991). Boyce et al. (1998) likewise found that monkeys with high inhibition scores suffered higher wounding rates when

placed in more stressful situations (e.g., social conflict, competition) compared to less inhibited monkeys. Comparable results found more recently by Capitanio et al. (2005) demonstrated that monkeys with low sociable scores exhibited abnormal HPA regulation and immune function when housed in an environment with frequent social conflict between group members. Understanding individual differences in temperament can thus greatly affect our understanding of the psychological well-being of these animals and inform housing and conservation efforts regarding group cohesion for social species in sanctuaries or managed care.

It is suggested that temperament should be considered in conservation programs such as reintroduction or relocation of an animal or species. Traits related to temperament and personality can aid efforts to identify individuals most likely to survive in the wild, and thus increase the success rate of such conservation programs. For example, swift foxes (*Vulpes velox*) were identified as exhibiting two temperament traits: bold and cautious. Cautiousness was shown to be more advantageous than boldness, as the bolder foxes were more likely to die within 6 months of being reintroduced into the wild (Bremmer-Harrison et al. 2004). In managed care facilities, introduction programs are also an important area where temperament can be greatly influential. For example, gorillas (*Gorilla gorilla*) with higher scores for extroversion and lower scores for dominance may be more likely to be placed in bachelor groups together in an exhibit without social conflict (Gold and Maple 1994). Understanding how environmental cues can influence temperament expression is also important for increasing the success rate of these introduction programs in both wild and managed care populations.

## Conclusion

This chapter highlights the application of temperament assessments to animal welfare, management practices, and health outcomes for a variety of vertebrate species. There is an increased need for more widespread application of temperament

assessments across species to better implement various conservation and management practices. While understanding an individual's temperament has been shown to help us predict how an animal may behave in both a social and nonsocial context, more work is needed to understand which dimensions of temperament are important or relevant to a given species. Furthermore, more research is needed to determine the distinction between the terms temperament and personality, as temperament is at times used to circumvent saying that nonhuman animals have personality. The use of behavioral syndromes in the terminology also should be addressed for how or if these terms refer to different components of behavior, as all terms typically refer to a pattern or group of behaviors consistent over time and across context (Sih et al. 2004). As our understanding of the temperamental constructs in animals increases, applications of temperament assessments will be more frequently incorporated to help researchers understand the individual differences present in the reactivity of an animal and increasing the welfare of animals at the individual and group level.

## Definition

The temporal bisection procedure is used to study temporal discrimination. Initially, the subject learns to choose between two response alternatives, R1 and R2, according to the (short = S1 or long = S2) duration of a sample stimulus: After S1, choose R1, and after S2, choose R2. Next, the experimenter introduces samples with new, untrained durations, and for each one, records the proportion of R2 (or “long”) choices. The psychophysical function relating the proportion of “long” choices to sample duration  $t$ , i.e.,  $p(\text{“long”}|t)$  reveals key properties of temporal discrimination.

## Introduction

Humans and animals can learn to adjust their behavior to the temporal attributes of the environment. A dog fed a bit of food every 30 min will come to salivate close to the moment the next food is due (Pavlov 1960). A rat that receives food every 60 s for pressing a lever, learns to pause for about 30 s and press the lever afterwards (e.g., Skinner 1938). An adult human can readily tell that a traffic light is red for longer than usual,

or that one phone call was shorter than another. The study of the sense of time of humans and animals has progressed considerably during the past and current centuries. One of the main procedures used to study it is the temporal bisection procedure.

## The Procedure and Typical Findings

Developed by Church and Deluty (1977) on the basis of Stubbs' (1968) and Catania's (1970) earlier work, the temporal bisection procedure instructs or teaches subjects to choose one of two responses, R1 and R2, following one of two sample stimuli, S1 and S2. Choice of R1 is correct/reinforced following S1, and choice of R2 is correct/reinforced following S2. Because S1 and S2 differ only in duration ( $S1 < S2$ ), to master the task, the subject must learn the temporal discriminations:  $S1 \rightarrow R1$  and  $S2 \rightarrow R2$ .

To characterize what the subject has effectively learned, the procedure then introduces generalization tests: On some trials, stimuli with novel durations,  $S_t$ , substitute for S1 and S2 (typically,  $S1 < S_t < S2$ ). These generalization tests may occur in extinction (choices are not reinforced), or under non-differential reinforcement (any choice after  $S_t$ , be it R1 or R2, is reinforced occasionally; e.g., Carvalho et al. 2016). The experimenter records the proportion of, say, R2 choices as a function of stimulus duration.

The procedural details depend on the species. With rats, S1 and S2 can be tones, noises, lights, or blackout periods, and R1 and R2 are typically two levers the animal can press (e.g., Church and Deluty 1977). With pigeons, S1 and S2 can be houselight or keylight durations, and R1 and R2 are typically two keys with different location or color that the birds can peck (e.g., Carvalho et al. 2016); with humans, S1 and S2 can be auditory or visual stimuli, and R1 and R2 are distinct keys in a computer keyboard (e.g., Wearden and Lejeune 2008). Animal studies tend to use durations spanning two orders of magnitude, from a few tenths of a second (S1) to a few tens of seconds (S2); human studies tend to use significantly shorter durations, from a few hundreds of

milliseconds to only a few seconds, partly to prevent counting during the sample. Whereas animals earn a small amount of food as a reinforcer for correct choices, humans earn points or verbal feedback ("Correct," "Good," etc.).

To analyze the data, the experimenter plots the proportion of R2 or "long" choices for each stimulus duration,  $t$ . The resulting psychometric function, denoted by  $p(\text{"long"}|t)$ , has a typical sigmoidal shape and increases from about 0 to about 1 as  $t$  ranges from S1 to S2. The left panel of Fig. 1 shows the average psychometric functions from Church and Deluty's (1977) seminal work with the bisection task.

The psychometric functions reveal some key properties of timing. First, the duration that yields indifference between R1 and R2 [i.e., the  $t^*$  such that  $p(\text{"long"}|t^*) = 0.5 = p(\text{"short"}|t^*)$ ] is generally interpreted as the duration that, for the subject, is equally distant from S1 and S2. That is, the interval from S1 to  $t^*$  seems equal to the interval from  $t^*$  to S2. Hence,  $t^*$  is called the Point of Subjective Equality (PSE). Moreover, because  $t^*$  may be interpreted as the point that, on the subjective scale for duration, divides the interval from S1 to S2 in two equal parts, it is also called the Bisection Point; hence, the procedure's name, Temporal Bisection. For animals, the PSE tends to be at the *geometric mean* of S1 and S2 ( $t^* \approx \sqrt{S1 \cdot S2}$ ), whereas in humans it tends to be at the *arithmetic mean* of S1 and S2 ( $t^* \approx (S1 + S2)/2$ ) (Church 2002; Richelle and Lejeune 1980).

Second, better temporal discriminations yield steeper functions, i.e., sigmoidal functions with higher slopes at the PSE or, equivalently, functions that rise from about 0 to about 1 in a shorter interval. The latter can be quantified by means of two durations,  $t_{q1}$  and  $t_{q3}$ , the durations for which the psychometric function equals 0.25 and 0.75, respectively (i.e.,  $p(\text{"long"}|t_{q1}) = 0.25$  and  $p(\text{"long"}|t_{q3}) = 0.75$ ). The two durations define the difference limen (DL),  $DL = (t_{q3} - t_{q1})/2$ . The smaller the DL, the faster the psychometric function rises. A subject with a smaller DL expresses greater sensitivity to the time dimension.

Third, for the same subject, the ratio DL/PSE (or an equivalent e.g., the reciprocal of the slope

**Temporal Bisection Procedure, Fig. 1** Left panel: Average psychometric functions obtained by Church and Deluty (1977) with rats using four sets of S1 and S2 values: 1 s versus 4 s, 2 s versus 8 s, 3 s versus 12 s, and 4 s versus

16 s. Right panel: Superposition of the psychometric functions after normalization of the time axis. (Reproduced with permission from the American Psychological Association)

of the function at the PSE divided by the PSE), a quantity akin to a Weber's fraction, tends to remain constant across bisection tasks. This and similar findings show that Weber's law applies also to temporal discrimination [but see Wearden and Lejeune 2008 for exceptions].

Fourth, bisection tasks using trained durations in the same ratio,  $k$ , (e.g., task 1:  $S1 = 1$  and  $S2 = 4$ ; task 2:  $S1 = 3$ ; and  $S2 = 12$ , for  $k = 4$ ) yield psychometric functions that superimpose when plotted in the same figure with the time axis normalized (i.e., divide all durations from a task by its  $S1$  or by the geometric mean of its  $S1$  and  $S2$  stimuli). The right panel of Fig. 1 shows this property. The superimposition of the psychometric functions reveals that temporal discriminations are relative to the trained durations. To put it more formally, if we let  $p(\text{"long"}|t, S1, S2)$  stand for the probability of choosing R2, given a test stimulus with duration  $t$  after mastering a task with stimuli  $S1$  and  $S2$ , then superimposition means that

$$p(\text{"long"}|t, S1, S2) = p(\text{"long"}|k \times t, k \times S1, k \times S2).$$

To illustrate, suppose that after mastering a bisection task with 1- and 4-s stimuli, a pigeon chooses "long" with probability 0.8 following a 3-s test stimulus. Then, after mastering another

task with 3-s and 12-s stimuli (i.e.,  $k = 3$ ), the same pigeon will choose "long" with probability 0.8 after a 9-s test stimulus. Superimposition of psychometric functions reveals the *scalar property* of timing (Church 2002; Wearden 2016).

Except for the location of the PSE, the foregoing properties of temporal discrimination have been observed in nonhuman and human animals (Church 2002; Richelle and Lejeune 1980; Wearden 2016), even though the procedural details vary (e.g., bisection experiments with humans generally use instructions, not primary reinforcers, to establish the initial discriminations; Wearden 2016). Thus, the basic processes involved in temporal discrimination may have substantial cross-species generality.

## Conclusions

The temporal bisection procedure has been extensively used to study how a host of different variables affects temporal discrimination. By manipulating the modality and nature of the sample stimuli, learning history and context, deprivation level, drugs, lesions, or the genetic makeup of the subjects, for example, and then examining

how these manipulations affect the psychometric functions, their PSE's, slopes, range of choice proportions, etc., a richer view of the sense of time of animals and humans has emerged. These studies have also helped researchers to develop better theoretical models of temporal discrimination.

[Temporal cortex](#)

## Definition

Temporal lobes are the part of gray matter (cerebral cortex) that is positioned behind the temples, on either side of head.

## Introduction

The temporal lobe has fascinated neuroscientists for several decades due to its role in memory and learning required for everyday activities. It is found only in primates. However, a few non-primate species possess a laterally expanded cortex that appears similar to the primate temporal lobe. The process of development in primates marked a specialization in visual information processing and object recognition, resulting in evolution of temporal lobe. In humans, the temporal lobe is

significantly expanded in comparison to the nonhuman primates including the apes.

## Evolution of Temporal Lobe

The presence of Sylvian fissure in ancestor *Smilodectes gracilis* suggested the presence of temporal lobe early in evolution in primates. *Aegyptopithecus*, an early fossil catarrhine that predates the divergence between hominoids (apes) and cercopithecids (Old World monkeys), is an example of an early fossil with superior temporal sulcus.

## Temporal Lobe in Nonhuman Primates

The temporal lobe is not developed in all nonhuman primates. A comparison between the temporal lobe anatomy of monkeys and dogs shows that in monkeys, the temporal lobe structures were highly interconnected. Information from cortical areas of temporal, frontal, and parietal lobes reaches perirhinal and parahippocampal cortical areas located on the medial temporal lobe which in turn project to the entorhinal cortex followed by the hippocampus. The amygdala also receives a strong projection from the entorhinal as well as perirhinal cortex. However, in dogs, the connections of neocortical areas to perirhinal, entorhinal, and parahippocampal areas are relatively unknown. Lesions of hippocampus result in impairment in spatial layout of an animal within its environment. In monkeys, the lesion in this area leads to impairment of memory for place. In rats with lesions to the perirhinal cortex, there is deterioration of spatial tasks. Recognition memory deficit due to involvement of temporal lobe in primates is still unclear. Recent studies in monkeys provide evidence that the rhinal cortex is critical for both object identification and memory (Bryant and Preuss 2018). Auditory recognition in animals is important for processing auditory information and communication. Studies on dogs have shown that they learn auditory memory tasks relatively easily as compared to monkeys who have difficulty learning auditory tasks.

## Temporal Lobe in Humans

In humans, temporal lobe is concerned with maintenance of visual memory, language comprehension, and emotion association by appropriately processing the sensory inputs. It derives the name as it sits inside the temporal bone (Fig. 1). The temporal lobe lies in the middle cranial fossa beneath the lateral fissure on both cerebral hemispheres. It is situated posterior to the frontal lobe and inferior to the parietal lobe. The greater wing of the sphenoid bone outlines it anteriorly. Inferiorly it is bound by the superior surface of the petrous part of the temporal bone, and laterally by the squamous part of the temporal bone and the adjoining parietal bone (Standring 2015).

The temporal lobe has four surfaces: lateral, medial, superior, and inferior. The *lateral surface* of temporal lobe consists of three parallel gyri, namely, superior, middle, and inferior temporal gyri (Fig. 2a). The lateral surface of the temporal lobe is separated by the superior and inferior temporal sulci (Mai et al. 2015). The lateral parietotemporal line separates the temporal and occipital lobes, and the occipitotemporal line

**Temporal Lobe, Fig. 1** The location of temporal bone in the human skull. Temporal lobe of the cerebral cortex derived its name from this bone. The other major lobes are also termed in similar forms

separates the temporal and parietal lobes (Fig. 2a). The superior surface consists of the planum polare, the anterior transverse temporal gyrus or Heschl's gyrus, and the planum temporale from anterior to posterior. This surface faces the Sylvian fissure, which is a very important landmark on the lateral surface of the cerebrum. The inferior surface consists of the inferior margin of the inferior temporal gyrus, the fusiform gyrus, and the parahippocampal gyrus from lateral to medial. These gyri are separated by the

occipitotemporal sulcus and the collateral sulcus (Kucukyuruk et al. 2012).

### Medial Temporal Region (MTR)

In humans, *medial surface* also known as the medial temporal region (MTR) is divided into three segments: anterior, middle, and posterior. Mostly the uncus and the entorhinal cortex form the anterior MTR (Fig. 2b). The middle MTR

**Temporal Lobe, Fig. 2** Schematic diagram of the human brain showing the margins of temporal lobe and associated structures in the brain. (a) *Lateral surface of the right cerebral hemisphere*. Region colored in yellow shows the temporal lobe with superior, middle, and inferior gyri. The orange colored line shows the boundaries of temporal lobe

separating it from the other lobes (Occipitotemporal line separates it from occipital lobe whereas parietotemporal line do the same from parietal lobe). (b) *Mid-sagittal view of left hemisphere*. The location of medial structures like medial temporal region (MTR) can be seen. Different gyri of temporal lobe are also shown

consists of parahippocampal gyrus, the dentate gyrus, and the fimbria of fornix, while the posterior end of the parahippocampal gyrus forms the posterior MTR (Fig. 2b) (Kiernan and Rajakumar 2013).

In animals, the medial temporal lobe manifests certain variations. In rhesus macaque, visual processing occupies greater cortical function as compared to rodents who rely mainly on olfaction. Perirhinal and postrhinal cortices of the rhesus macaque receive primarily visual type cortical inputs, while in the rodent inputs to these regions are distributed more evenly across all sensory modalities. The entorhinal cortex receives direct projections from the olfactory bulb in the rodent resulting in superior that olfactory system in the rodent.

### **White Matter Associated with Temporal Lobe**

Bundles of white matter called fasciculus connect the distant association areas. There are seven fasciculi in humans and six in macaques. One of the most important is arcuate fasciculus. It provides a two-way communication between frontal cortex, including Broca's expressive speech area, and Wernicke's receptive language area in the posterior part of the superior temporal gyrus. Conduction aphasia is traditionally attributed to a destructive lesion that interrupts the arcuate fasciculus. It is poorly developed in macaques and restricted only to superior temporal gyrus in chimpanzees.

Another fasciculus that connects frontal, parietal, occipital, and temporal lobe is the cingulum bundle. It traverses close to cingulate gyrus. It is concerned with memory, emotions, and attention and has been studied both in human and primates. The inferior longitudinal fasciculus is an important source of fiber afferent to the amygdala. It connects the visual areas with one another and also to the temporal polar cortex (Kiernan 2012). It is found in both humans and chimpanzees. Others include the uncinated fasciculus that is a frontotemporal association bundle and the middle longitudinal fasciculus.

### **Important Structures in Temporal Lobe**

**Hippocampus:** This is one of the important structures located in the medial temporal lobe of the cerebrum. The structure is compared to a seahorse due to its shape. It forms an important part of the limbic system and has a vital role in long-term memory and spatial navigation. It is one of the first regions of the brain to get affected in patients suffering from Alzheimer's disease. The hippocampus is also important in the formation of new memories. Researchers have also established the role of the hippocampus in long-term memory. In cases of damage, patients might experience retrograde amnesia that affects memories formed before the damage or anterograde amnesia that is difficulties in forming new memories. However, ability to learn new motor or cognitive skills is preserved (Bird and Burgess 2008).

The role of hippocampus in the development of cognitive map of the environment was recognized with the discovery of place cells in the 1970s. A common observation in amnesia patients is getting misplaced and forgetting their original location. This has been studied extensively in animals (Rosene and Van Hoesen 1987) including humans. It is understood that humans and animals approach similar tasks using multiple memory systems. For example, habit learning of a task occurs most commonly in monkeys in comparison to humans who memorize stimulus material. Behavioral impairments observed in rats with hippocampus lesions are not similar to memory impairment seen in humans with hippocampal damage. Damage to the hippocampus can also result from oxygen starvation (hypoxia), encephalitis, or medial temporal lobe epilepsy.

**Amygdala:** It consists of a group of heterogeneous nuclei located within the temporal lobe. It receives inputs from a wide variety of both cortical and subcortical areas of the brain. It receives information from visual system, auditory, olfactory, and gustatory and somatosensory cortices. In addition, it also receives projections from association cortex, the thalamus and hippocampus. It is involved in emotional learning, modulation of memory, and emotional influences on social behavior and decision-making via its

interactions with the prefrontal cortex and the hippocampal system. Studies with monkeys and rodents have shown that, like humans, stronger stimuli result in greater activation of the amygdala. This affects fear conditioning and sensing danger (Rosen and Donley 2006). It has a role during fear conditioning in humans where sometimes a freezing response occurs in a potentially threatening situation. It is also involved in memory formation and retrieval, and affective processing in humans. It also participates in semantic encoding and discrimination between familiar and novel stimuli.

## Disorders of Temporal Lobe

1. Klüver-Bucy syndrome (KBS) was first described in monkeys. Experimentally bilateral temporal lobectomy was performed in monkeys while it was done in humans (Terzian and Dalle Ore 1955) who had intractable epileptic. The diagnosis is based on the presence of any three of the following symptoms of hyperorality (a strong tendency to examine all objects orally), indiscriminate hypersexuality, visual agnosia (a psychic blindness of inability to recognize objects without a loss of gross visual discrimination), and serenity with loss of normal fear and anger.
2. *Disorders of Auditory Perception* – The auditory cortex helps in discriminating two forms of auditory processing, i.e., rapidly processing stimuli and complex stimuli pattern. Patients with temporal lobe lesions have difficulty in discriminating speech sounds. There is also an impairment of the temporal order of sound. Auditory hallucinations as a result of spontaneous activity in the auditory regions lead to perception of sounds that are not actually present. Wernike's aphasia characterized by inability to recognize words occurs due to lesions of left temporal association cortex (area number 22). Bilateral lesions lead to cortical deafness.
3. *Disorders of Music Perception* – Patients with temporal lobe lesions have deficit in processing musical sounds. Lesions of right temporal lobe result in impaired pitch discriminations. The perception of timbre, which refers to the distinctive character of sound at the same note and loudness, is also impaired in right temporal lesions. Rhythm discrimination is most commonly affected by right posterior superior temporal gyrus damage.
4. *Disorders of Visual Perception* – Prosopagnosia also known as face blindness, can occur following damage to temporal lobes particularly right temporal lobe, is the inability to recognize familiar faces (including one's own face) or photographs of faces. However, these individuals are perfectly aware that some sort of visual stimulus is present and can describe particular aspects or elements of it without difficulty.
5. *Disorders of Memory* – Damage to left temporal lobe results in impaired recall of verbal material presented in visual or oral form whereas damage to right temporal lobe results in impairment of recall of nonverbal things such as drawings, tunes, faces, etc. As stated previously, removal of medial temporal lobe including hippocampus and amygdala leads to amnesia.
6. *Disturbance of Selection of Visual and Auditory Inputs* – In cases where more than one auditory information is presented simultaneously, there is difficulty in focusing selectively on the input onto one ear or all inputs concurrently. Similarly, if two different visual stimuli are present simultaneously one to each visual field, there is impaired recall of content of both visual fields when right temporal lobe is damaged. In case of damage of left temporal lobe, there is deficiency in recalling of right visual field contents.
7. *Disturbances in Organization and Categorization* – The ability to organize and categorize information are important for language and memory. The patients with left temporal involvement have difficulty in placing words or pictures into discrete categories. For example, apple, banana, and mango belong to the category "fruits."
8. *Disturbances in using contextual information*, in extracting information from the environment and using visual and social cues.

## Definition

A teratogen is an agent that disrupts the normal embryonic development and induces developmental abnormalities in animals. The term teratogen is derived from the Greek word “*teratos*” meaning monster. Teratology is the study of abnormalities of physiological development.

## Types of Teratogen

A teratogen can be a physical, chemical, or biological agent. X-rays and other harmful radiation are examples of physical teratogens. Chemical teratogens are drugs like cyclophosphamide, lithium, thalidomide, and retinoic acid and some metabolites in maternal blood like phenylalanine and alcohol. Absence of metabolites like folic acid also produces teratogenic effect. Biological teratogens are rubella virus, herpes virus, toxoplasma, etc.

## Effect of Teratogen

The effect of teratogen is determined by the developmental stage of the fetus. Teratogen exposure during the first week of gestation

(predifferentiation stage) has all or none effect. It can either lead to abortion or no effect at all. Teratogen exposure during organogenesis leads to congenital malformation.

## Teratogenic Drugs

A teratogen can have effect on different tissues, and many teratogens can produce same effects (Twining's Textbook of Fetal Abnormalities 2015). Some teratogens are associated with peculiar morphological features as listed in the table.

| Teratogenic drug | Medicinal use                                                                                                                              | Associated deformity                                                                                         |
|------------------|--------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------|
| Thalidomide      | Morning sickness (discontinued), the drug has been repurposed as immunomodulator for use in multiple myeloma and erythema nodosum leprosum | Phocomelia (foreshortening of the arms), Amelia (lack of arms), Microtia (small ears), Anotia (lack of ears) |
| Carbimazole      | Hyperthyroidism                                                                                                                            | Choanal atresia, Cutis aplasia with distinctive facial features                                              |
| Warfarin         | Anticoagulant                                                                                                                              | Hypoplastic nose, Brachydactyly (short-fingers), Scoliosis                                                   |
| Aspirin          | Non-steroidal anti-inflammatory drug with anti-platelet effect                                                                             | Gastroschisis (Abdominal wall defect with protrusion of intestines out)                                      |
| Aminoglycosides  | Antibiotic                                                                                                                                 | Hearing loss                                                                                                 |
| Valproate        | Anticonvulsant                                                                                                                             | Spina bifida (part of the spinal cord and meninges are exposed through defect in the vertebrae)              |
| Lithium          | Bipolar disorder (patient goes through manic and depressive phases)                                                                        | Cardiac malformations                                                                                        |
| Tetracycline     | Antibiotic                                                                                                                                 | Yellow staining of teeth                                                                                     |
| Isotretinoin     | Acne (Pimples)                                                                                                                             | Cleft palate, Neural tube defect                                                                             |

US Food and Drug Administration (FDA) categorized therapeutic drugs into five groups based on their teratogenic potential to be used in pregnant women (FDA Pregnancy Categories 2019).

1. Category A – Controlled studies in humans have shown no risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters).
2. Category B – Animal studies have shown no risk to the fetus. No controlled studies have been conducted in humans.
3. Category C – Animal studies have shown an adverse effect on the fetus and there are no controlled studies in humans.
4. Category D – There is positive evidence of human fetal risk based on the adverse reaction data, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
5. Category X – Animal or Human studies have demonstrated fetal abnormalities or there is positive evidence of human fetal risk based on the adverse reaction data and risk involved in the use of drug in pregnant women clearly outweigh potential benefits.

Apart from the therapeutic drugs, Illicit use of nicotine, alcohol, and cocaine is also associated with teratogenicity. Intake of alcohol by pregnant mothers lead to fetal alcohol syndrome in the baby. Ethanol competes with the retinol for the conversion by alcohol dehydrogenase and thus affects the retinoic acid synthesis and thus disrupts the retinoic acid signaling pathway. Nicotine from cigarette smoke causes vasoconstriction of placental vessels and decreases the blood supply to fetus leading to intra uterine growth retardation and mental retardation.

## Biologic Teratogens

Infection with rubella (German measles) leads to the triad of cataract (opacity in the lens of the eye), hearing loss, and cardiac malformations (Yazigi et al. 2017). Infants of mothers with diabetes mellitus are prone to develop congenital heart diseases and neural tube defects (Ornoy et al.

2015). Infants of mothers with phenylketonuria develop mental retardation.

Teratogenic Plants

Certain plants have been found to contain teratogenic chemicals. Keeler (1984) has classified teratogenic plants in the following way (Keeler 1984). Cattle grazing on these plants are susceptible to produce offspring with congenital malformations.

| Class                                                 | Example                                        |
|-------------------------------------------------------|------------------------------------------------|
| Known teratogens in known teratogenic plants          | Lupinus, Veratrum, Conium, and Leucaena genera |
| Known teratogenic plants with unidentified teratogens | Astragalus, Nicotiana, and Trachymene genera   |
| Suspected teratogenic plants                          | Datura, Prunus, Sorghum, and Senecio genera    |

University (UNESP), Rio Claro, São Paulo, Brazil

Synonyms

Land animals; Terrestrial animals

Definition

Terrestrial can be defined as the variety of life forms and adaptation on the land surface of the Earth (Laurin 2010).

Introduction

Terrestrial animals spend most of or their entire life span on land, in contrast to animals that live predominantly in water. Free living species in terrestrial environments are represented by the following ten phyla: flatworms (planarians), Nemertea (ribbon worms), Nematoda (roundworms), rotifers, Tardigrada (water bears), Onychophora (velvet worms), arthropods, mollusks (gastropods: land snails and slugs), Annelida, and Chordata (tetrapods). Examples of terrestrial animals include turbellarian, nemertean, cats, ants, dogs, raccoons, spiders, kangaroos, tigers, lions, mice, bats, bulls, oxen, leopards, elephants, birds, and many more (Fig. 1).

The context

Animals had previously lived only in the oceans but, starting during the Cenozoic approximately 470 million years ago, began to colonize the previously barren continents. The terrestrial invasion of animals is a significant event in evolutionary context (Shear 1991). Terrestrial lineages evolved in several animal phyla, among

**Terrestrial, Fig. 1** Example of the variety of life forms and adaptation on the land surface of the Earth. (A) The Leaf Frog (*Phyllomedusa distincta*) lives inside moist primary and secondary forest, and on the forest edge. (B) The orb-weaver spider (*Wagneriana* sp.) are the most common group of builders of spiral wheel-shaped webs often found in gardens, fields and forests. (C) The jaguar (*Panthera onca*) habitat is typically characterized by dense forest cover (mainly primary and secondary forest), the presence of water bodies and a sufficient prey base. (D) The Ihering's fathead anole lizard (*Enyalius iheringii*) lives mainly in arboreal habitats and found on vegetation as well as in the ground. (E) The Boulenger's Tree Snake (*Sibynomorphus mikanii*) predominant habitat type in the

species' range is savanna which may be active both by day and at night. (F) The Mountain Lion (*Puma concolor*) is an adaptable cat, being found in every major habitat type of the Americas, including the high Andes. (G) The howler monkey (*Alouatta caraya*) is found in semi-deciduous forests and can adapt to disturbed and degraded habitats. (H) The great horned owl (*Bubo virginianus*) may be found in a number of woodland habitat types across this species' wide range, from cold evergreen woodland in the far north and south to humid tropical forest near the equator. (I) The Blue-and yellow Macaw (*Ara ararauna*) are found in wooded areas, often near water and sometimes forage in more open sites, coming to the ground to feed on fallen fruits (photos by M. N. Godoi and A. Piva)

which arthropods, mollusks, annelids, and vertebrates are representatives of more successful groups of terrestrial animals. The first direct evidence from animal fossils come from the myriapods (centipedes and millipedes), followed by other arthropod groups and vertebrates (Little 1983; Clark 2002).

A more likely hypothesis is that these early arthropods' motivation for venturing onto dry land was to mate (as modern horseshoe crabs do)

or lay eggs out of the reach of predators (Cloudsley-Thompson 1988). As time went on, evidence suggests that the bony fish best adapted to life in shallow coastal/swampy waters (such as *Tiktaalik roseae*) were much more viable as amphibians than were their arthropod predecessors. When animals colonized terrestrial habitats, they had to adjust to the fluctuating temperatures, the replacement of water with air, and the increased level of oxygen. Terrestrial animals

adapted to these challenges by developing different metabolic systems, employing thermoregulatory behaviors, and developing desiccation-resistant skin or exoskeletons. In addition, terrestrial animals have to deal with the nitrogenous waste products; fish (and amphibians) produce ammonia, a highly toxic compound but highly soluble in water, while reptiles, birds, and mammals excrete urea and uric acid, less toxic compounds that require less water to be excreted. Other adaptations in animals include the development of internal fertilization; olfactory, hearing, and vision organs; structures for movement; and complex behavior (Little 1983).

### **Focusing on Arthropods and Tetrapods to Understand Terrestrial Animals Cognition and Behavior**

#### **Arthropods (Terrestrial)**

There are five kinds of terrestrial arthropods: crustaceans, millipedes, centipedes, arachnids (mites, ticks, spiders, scorpions), and insects. Flightless insects also are early terrestrial organisms. The exoskeleton of marine arthropods was important in allowing some of their descendants to adapt to land. It provides the support needed in the less buoyant air and serves as a surface for muscle attachment that permits rapid movement. The exoskeleton of most terrestrial arthropods has a waxy coating that reduces water loss. Another important method of conserving water in insects and spiders is the presence of Malpighian tubules, thin-walled tubes that surround the gut and reabsorb water from nitrogenous wastes prior to their excretion.

Internal fertilization is typical of terrestrial arthropods and involves copulation, in which a penis is used to insert the sperm into the reproductive tract of the female (insects, millipedes) or the production of special sperm-containing sacs (spermatophores) that are picked up by the female (spiders, centipedes). This is important mechanism because both the sperm and egg are protected from drying. Moreover, terrestrial arthropods have complex life cycles that involve larval stages that occupy different niches from the adults.

Terrestrial arthropods have evolved a number of characteristics that assure their survival under hostile environmental conditions. Many seek out sheltered sites and become inactive during periods of cold or drought. Often this involves changes in physiology that protect against freezing or prevent water loss. The terrestrial arthropods occupy an incredible variety of niches. Many insects are herbivores that compete directly with humans for food. Other kinds of insects, as well as spiders and centipedes, are carnivores that feed primarily on arthropods and other small animals. Mites and millipedes feed primarily on decaying material and the fungi and bacteria that are part of decaying material. Insects have evolved in concert with the flowering plants; their role in pollination is well understood. Bees, butterflies, and beetles transfer pollen from one flower to another as they visit the flowers in search of food. Many kinds of crops rely on bees for pollination, and farmers even rent beehives to ensure adequate pollination for fruit production.

#### **Chordata (Tetrapods)**

**Amphibians** The conquest of land was not done from 1 day to the other; it was possible with the combination of multiple adaptations. Some of the most important characteristics that allowed the first amphibians to leave the water were the evolution of lungs, which are homologous to the gas bladder that allows fish to control its buoyancy. Lungs appeared as an additional way to get oxygen from the air. In fact, there is actually a sarcopterygian family the members of which have lungs to get oxygen from the air, for they live in waters poor on oxygen. Development of the choanae, or internal nostrils, was another important characteristic; while fish present a pair of external nostrils at each side of its snout through which water passes on while swimming, the ancestors of the tetrapods only had one external nostril at each side connected to the internal nostrils, the choanae, which communicated with the mouth. This allowed them to get air through their noses using lung ventilation and this way to smell outside of water. Another characteristic was the apparition of the quiridium-like limb,

the most basic characteristic in tetrapods. This limb is known for having the differentiated parts: the stylopodium (one bone, the humerus or the femur), the zeugopodium (two bones, the radius or tibia and ulna or fibula), and the autopodium (fingers, hands, toes, and feet). While the stylopodium and zeugopodium derived from the sarcopterygian's fins, the autopodium is a newly evolved structure exclusive from tetrapods.

**Reptiles** All living reptiles share certain fundamental characteristics, features they retained from the time when they replaced amphibians as the dominant terrestrial vertebrates (Little 1983; Cloudsley-Thompson 1988). Among the most important is amniotic egg. Amphibians never succeeded in becoming fully terrestrial because amphibian eggs must be laid in water to avoid drying out. Most reptiles lay watertight eggs that offer various layers of protection from drying out. The reptilian amniotic egg contains a food source (the yolk) and a series of four membranes – the chorion (the outermost layer), the amnion (the membrane surrounding the embryo), the yolk sac (containing the yolk), and the allantois (the red structure). Amphibians breathe by squeezing their throat to pump air into their lungs; this limits their breathing capacity to the volume of their mouth. Reptiles developed thoracic breathing, expanding and contracting the rib cage to suck air into the lungs and then force it out. In addition, reptiles improved on the innovations first attempted by amphibians. Legs were arranged to more effectively support the body's weight, allowing reptile bodies to be bigger and to run. Also, the lungs and heart were altered to make them far more efficient.

**Birds** The reptiles gave rise to two other groups of vertebrates: birds and mammals (Shear 1991; Clark 2002). About 65 million years ago, a mass extinction of many kinds of reptiles occurred. At that time, birds and mammals began to diversify and became the dominant forms of vertebrates on land. Like the structures of their reptile ancestors, the skin, lungs, and kidneys of birds reduce water loss, and reproduction involves internal fertilization and the shelled amniotic egg. They also have other adaptations that allow them to be successful

as land animals. Birds are homeothermic and have feathers. As homeotherms, they have a high body temperature and a more rapid metabolic rate than reptiles. The exploitation of flight has shaped the entire structure and function of birds. The forelimbs are modified into wings for flight, although it is actually the flight feathers that provide most of the flight surface. Large breast muscles provide the power for flight. Feathers help provide a streamlined shape. Homeothermism enables a high constant temperature, which allows for the rapid wing beats typical of most birds. In addition, the skeleton is reduced in weight, and the jaws lack teeth that are heavy. Birds have successfully occupied many niches. Some are nectar feeders, some are carnivores, some are seedeaters, some are aquatic, and some have even lost their ability to fly.

**Mammals** The first mammals appeared about 200 million years ago, when reptiles were at their most diverse (Shear 1991; Clark 2002). Like birds, mammals are homeotherms, with a high constant body temperature. Like reptiles and birds, they have a waterproof skin and water-conserving lungs and kidneys. However, they differ from birds in several respects. Their insulating covering is hair, rather than feathers, and they provide nourishment to their young with milk produced by special glands. Scientists classify mammalian reproduction into three categories: (i) monotremes (platypus and echidna) are egg-laying mammals whose young still develop in an external egg; (ii) marsupials have pouches, where the young are born in an immature stage and are carried in the pouch while they finish their development; and (iii) placental mammals have a placenta, which connects the mother and embryo; they retain the young in the uterus for a longer period of time.

**Mode of Life** On the basis of their mode of life, terrestrial animals are divided into following types:

- (i) Cursorial which live in open places and are adapted to run on hard ground, e.g., lion, deer, and horse. Adaptational characters of

them are the body streamlined which helps them for swift movement. The limbs are long and strong and the locomotion is digitigrade.

- (ii) Fossorial which are adapted for burrowing mode of life, e.g., rabbit, rat, etc. The adaptational characters of fossorial animals are the head, eyes, and ears that are small and tapers anteriorly to form snout for digging. The forelimbs are short with powerful claws and the eyes and the ears are small.
- (iii) Arboreal which are adapted for climbing, e.g., squirrel, chameleon, etc. The adaptational characters of these animals are the body is stout, ribs are very much curved, thus thorax becomes semicircular, the muscles of chest are very strong, and the locomotion is classified plantigrade.
- (iv) Aerial that are adapted for aerial mode of life, e.g., bats. The adaptational characters of aerial animals are body is streamlined, which reduces the air resistance during flying. Forelimbs are modified into wings, the bones are hollow and spongy, and the eyes are very sharp and well developed.
- (v) Desert animals are adapted for dry land and hot habitat, e.g., camel, lizard, rodents, etc. The desert animals are provided with keen senses of sight, smell, and hearing. They conserve water in water pouches and have thick skin to avoid loss of water. Most of them have dull color which blends them with the surrounding environment.

## Conclusion

The term terrestrial in biology is generally used to describe living organisms that live and grow on land. Living things that make use of nature as their habitat may be grouped based on where they live, grow, and reproduce. Living things that spend most of their life on land are called terrestrial. This is in contrast to living things that live on water (called aquatic) and those that are not growing in the ground (called aerial or epiphytic, especially of plants). Labeling an animal species “terrestrial” or “aquatic” is often obscure and becomes a matter of judgment. Many animals

considered terrestrial have a life cycle that is partly dependent on being in water. Otters, sea lions, and penguins sleep on land and feed in the water, yet they are all considered terrestrial. Many arthropods, e.g., dragonfly and crabs, as well as amphibian, e.g., frogs, toads, newts, salamanders and other clades, have an aquatic life cycle stage. High terrestrial biodiversity is often used as an indicator of ecosystem health and has been shown to have direct links to human health. Anthropogenic disturbance will affect terrestrial biodiversity and ecosystems (Dirzo et al. 2014; Gonçalves et al. 2017) through both gradual and sudden changes in response to the average climate and land use change (e.g., increased temperatures, decreased rainfall, changes to seasonality, loss of habitat) and extreme events (increased hot days, fire, increased frequency and severity of cyclones, heat waves, intensified wet seasons).

Southern Maine, Portland, ME, USA

## Synonym

Resource defense; Territory

## Definitions

Territoriality refers to maintenance of a territory and thus includes territorial behavior, at the individual level, and spatial patterns that result from those individual interactions, at the population level (Hinsch and Komdeur 2017). However, territory may be defined conceptually in many ways (Maher and Lott 1995). The most common conceptual definitions can be grouped into one of three categories, and they illustrate the difference in emphasis between ecological and behavioral aspects of territoriality: defended area, exclusive area, and site-specific dominance. The oldest definition, defense (Howard 1920), reflects a focus

on interactions that produce the outcome, whereas use of an exclusive area (Pitelka 1959) highlights the outcome rather than the process. A researcher's choice of definitions often reflects the taxonomic group and habits of species being studied (Maher and Lott 1995). Thus, scientists studying more easily observed species such as fish, birds, dragonflies, ants, and large mammals often use definitions relating to defense, whereas people studying more secretive, nocturnal species such as small mammals rely on measures of exclusive use.

In addition to conceptually defining territory, it is important for researchers to operationally define the term, providing explicit criteria by which they measure space use or defense in animals, e.g., amount of spatial overlap or rate and location of aggressive interactions. Because spacing systems actually represent a continuum, such criteria enhance the ability to compare spatial organization within and across species.

## Introduction

Territoriality can be viewed as both an ecological and a behavioral concept. Exclusive use of space leads to more or less uniform distribution of organisms across the landscape, with implications for population-level phenomena such as density-dependent regulation of population sizes. However, territoriality also is a behavioral concept because the mechanisms that produce exclusive use of space involve behavior patterns. To maintain a territory, animals interact with each other, whether subtly through scent marks and threat displays or more overtly through chases and fights.

In reality, territoriality is one type of spacing system that falls along a continuum (Maher and Lott 1995, 2000). Thus, animals can be more or less territorial depending on how sharply boundaries are defined or how often territory owners engage and exclude intruders. Territoriality may lie at one end of the continuum, and other alternative social systems lie at the other end, depending on one's perspective. From an ecological view, animals may exhibit a range of space

use extending from maintaining exclusive areas to completely overlapping home ranges. A more behavioral approach may view the continuum as ranging from territoriality at one end to a dominance hierarchy at the opposite end. By incorporating multiple dimensions, reflecting elements of space use, behavior patterns, and time, researchers can gain more realistic views of the flexibility of territoriality.

Much of the literature on territoriality is focused on vertebrates, and territoriality has been described in almost all vertebrate taxa, including bony fish, amphibians, lizards, crocodilians, birds, and mammals. Furthermore, territoriality occurs in many insect taxa, including bees and wasps, ants, flies, and odonates, as well as crustaceans, spiders, molluscs, and anemones.

As is true for many biological phenomena, researchers can study territoriality using different approaches. Scientists may emphasize ultimate questions such as the fitness consequences of maintaining a territory or the ecological and social conditions under which an animal defends a space. Researchers also may examine proximate mechanisms such as the hormonal control of behavior that produces territoriality or the role of learning in establishing a territory. Both approaches have enhanced our understanding of this widespread and diverse phenomenon.

## What Is Defended and Why?

Territories often are contrasted with home ranges, i.e., areas where animals conduct their daily activities (Howard 1920). Unlike home ranges, territories are defended, and neighboring individuals do not overlap in their use of space. Territories contain some limited resource and thus afford the owner more or less exclusive access to that resource. These areas may be designated as “all purpose” if they contain multiple resources such as food and reproductive sites including nests or dens, or they may serve more specific roles if territories contain solely food (a feeding territory, e.g., nectarivorous birds), nest sites (e.g., colonial birds), or oviposition sites (e.g., dragonflies).

Maintaining exclusive access to resources and defending them against other individuals involve both costs and benefits to the territory owner. Clearly, sole access to limited resources within a territory provides benefits. Furthermore, because territories distribute animals across the landscape, risk of predation, parasitism, or disease may be lower (Huntingford and Turner 1987). However, costs include time and energy spent acquiring the territory initially, which may involve removing the previous owner, and then maintaining exclusive access, including defending the area against subsequent intruders with its risk of injury, patrolling and demarcating boundaries, and lost opportunities to do other things (e.g., feed or mate) while patrolling or defending the territory. Ideally, these costs and benefits are measured in units of fitness; however, in reality, they may be measured in units of time or energy gained or lost.

The classic cost-benefit model of territoriality dates back to Brown (1964), with its focus on economic defensibility. For natural selection to favor territoriality, benefits must exceed costs, and both resources and population density play key roles in determining those costs and benefits. Thus, when resources are scarce, benefits to maintaining exclusive access are low, and costs are high because an animal must maintain a relatively large area to secure sufficient resources. Similarly, when resources are superabundant, an area may contain more resources than an individual could use, again making defense unprofitable. Population density or intruder pressure also must be considered. At high densities, the costs of repelling repeated incursions might not justify the benefits afforded by those resources. Thus, we expect territories to be maintained at intermediate levels of resource abundance and population density.

Early in the history of the field of behavioral ecology, social systems commonly were viewed as fixed attributes of species, e.g., members of a species either were territorial or they maintained undefended home ranges or established a dominance hierarchy. However, as the discipline developed and field observations proliferated, researchers came to view social systems, including spacing systems, as more flexible, with

members of the same species displaying different types of social systems across different populations or within the same population over time (Lott 1991). Indeed, members of some species may shift space use on the scale of hours or days, e.g., rufous hummingbirds (*Selasphorus rufus*), golden-winged sunbirds (*Drepanorhynchus reichenowi*), and pied wagtails (*Motacilla alba*; Davies and Houston 1981).

Such flexibility is related to economic defensibility. Presumably, as cost-benefit ratios shift, animals adjust their behavior, and the spacing system changes accordingly. Many such reports of intra-specific variation relied on observations of changes in an ecological variable such as food abundance or population density, which then correlated with a change in the spacing system. Fewer studies manipulated variables experimentally and then measured the behavioral response. Nonetheless, such experimental work sometimes revealed that resources, primarily food and population density, can produce shifts between territoriality and another outcome such as undefended home ranges. Yet, other experimental studies produced no such changes, perhaps because other, unrecorded variables affected the outcome (Maher and Lott 2000). To test economic models of territoriality, it is essential to provide operational definitions of territoriality with quantified variables measured over spatial and temporal scales that are relevant to the animals (Maher and Lott 1995, 2000). Furthermore, alternative ways of analyzing data, including model selection (Burnham and Anderson 2002), offer useful ways of evaluating combinations of variables and their effects on spatial organization.

Characteristics of food (e.g., abundance, distribution, renewal, predictability, and quality) are widely considered as potential determinants of territoriality. Perhaps food actually is an important resource; however, these studies may reflect logistical constraints, especially in field studies. Food is relatively easy to manipulate and measure, and animals are easier to observe when they feed. Certainly, food is important to animals, particularly for species with high energetic demands such as nectarivorous birds. Yet, other variables may be more important in other taxa (Maher and Lott 2000).

In general, the relationship between food abundance and territoriality and between food distribution and territoriality is not linear but instead shows an inverted U-shaped distribution (Maher and Lott 2000). Thus, as the amount of food increases from low to medium levels, territoriality increases, whereas as food levels increase further from medium to high levels, net benefits of maintaining exclusive access to food decrease, reducing territoriality. Similarly, when food is highly clumped or evenly distributed, it is not economically defensible, whereas moderately clumped resources can be defended. Ideally, researchers quantify food levels or patterns of distribution as well as behavior patterns associated with territoriality to capture gradual shifts in behavior rather than a more simplistic on-off, either-or function.

In contrast to food abundance and distribution, the relationship between food predictability and territoriality is expected to be linear. Thus, when food is spatially or temporally predictable, it can be defended more easily. Species that cache food to guard against temporally unpredictable conditions can create a more predictable resource and thus defend caches (Maher and Lott 2000).

Population density also is widely reported as determining degree of territoriality. Similar to some characteristics of food, the relationship between population density and territoriality is expected to show an inverted U-shaped distribution. As noted above, at low densities, the presence of few competitors does not justify defense of an area, and at high densities, frequent intrusions raise the costs of defense relative to benefits. Thus, intermediate population densities are associated with territoriality. Although many studies support this prediction, reports sometimes contradict each other. Such contradictions may result from the design of the study, importance of other, unrecorded variables, or a lack of clarity in terms of what constitutes “high” and “low” density (Maher and Lott 2000).

Economic models of defensibility provide a useful framework for understanding when an animal should maintain a territory. However, researchers also recognize that territorial behavior involves more than just the territory owner. It also includes

the intruder, which must decide whether or not to intrude. Such decisions bear fitness benefits, such as access to the resource, but also costs, such as risk of injury. Thus, game theory can be used to understand the behavior of both owner and intruder simultaneously (Hinsch and Komdeur 2017).

In addition to decisions about defending or not defending an area, the territory owner also must decide how much area to maintain as a territory. The largest territories (many hectares) belong to large mammals that defend all-purpose areas containing sufficient food resources, whereas the smallest territories (a few square meters) occur on leks, which are display areas containing multiple males that occupy small exclusive areas solely to attract a mate for copulation. Once again, benefits and costs play important roles in determining territory size. Initially, benefits increase as the size of a territory increases and animals secure more resources. However, there are limits on what one individual can use or consume, such that additional resources do not yield additional benefits. Furthermore, costs also increase with territory size. A larger area requires more time and energy spent patrolling longer boundaries, detecting and repelling intruders (Davies and Houston 1984). Indeed, animals may adjust territory size over short (daily) time scales to maximize energy gains (Carpenter et al. 1983; Gill and Wolf 1975).

In some cases, the ratio of benefits to costs allows a territory owner to tolerate satellites on the territory, i.e., the owner does not chase away intruders. In exchange for help in defending the territory, the satellite obtains food resources (Davies and Houston 1981). Although the owner loses some food to the satellite, it gains assistance in defending the territory against additional intruders. Thus, when food resources are abundant, an owner may tolerate a satellite in exchange for help, and when food is less abundant, the owner evicts the satellite.

## Who Defends and When?

Some animals maintain territories year round, because they rely on resources such as food

provided continuously by the area, and territories remain economically defensible throughout the year. However, in many species, territoriality is seasonal, and it often coincides with the breeding season. Moreover, across species, if sexes differ in territoriality, males often are more territorial than females, excluding other males from the area, and males defend a resource that females seek. For example, male dragonflies and damselflies defend oviposition sites that females use, and in numerous polygynous bird species, males defend nesting sites. As noted earlier, the smallest territories occur on leks, breeding grounds where males display in groups, with each male defending a small space on the lek. Females arrive from surrounding areas, assess and choose mates, and then depart. Males provide no resources or parental care. Leks are best known in birds; however, they occur in some mammals, amphibians, lizards, fish, and insects.

In some species, females maintain territories, typically excluding other females. Although the function may be to secure adequate resources for their young, territories also may protect against infanticidal conspecifics (Wolff and Peterson 1998).

Territories most commonly are held by individuals. Nevertheless, a male-female pair or a group may jointly defend an area. Many songbirds pair up during the breeding season and defend a territory against other pairs. Group territories occur across a range of social insects (e.g., ants), birds (e.g., acorn woodpeckers, *Melanerpes formicivorus*; Florida scrub jays, *Aphelocoma coerulescens*; Seychelles warblers, *Acrocephalus sechellensis*), and mammals (e.g., alpine marmots, *Marmota marmota*; European badgers, *Meles meles*; lions, *Panthera leo*), and individuals breed cooperatively within those areas.

Finally, territories can be defended not only against conspecifics but also against heterospecifics. When species that have similar territorial behavior patterns (i.e., song or displays) first make contact, individuals may mistake each other for conspecifics. Thus, interspecific territoriality is a case of mistaken identity and a nonadaptive result of intraspecific territoriality. Natural selection is expected to eliminate such behavior if costs

of defense exceed benefits of excluding these heterospecific intruders. However, in some cases, closely related species compete for similar resources, including food and mates (Losin et al. 2016). Coral reef fishes maintain territories against individuals of other species that compete for similar food resources in a limited area. Furthermore, closely related species may hybridize, such that reproductive interference may explain other cases of interspecific territoriality (Drury et al. 2015).

### Proximate Mechanisms

Key aspects of territoriality include use of exclusive space and defense. Thus, territory owners must inhibit intruders in some way to ensure exclusive access to resources, and such inhibition often involves agonistic interactions between intruders and residents. These interactions may range from subtle avoidance to threat displays to overt fighting. Furthermore, residents and intruders may not meet physically, and cues may be enough to keep intruders from encroaching into a territory. As a result of the interaction, one individual wins the encounter, usually the resident. Researchers have explored the proximate basis for territoriality, including why residents win, how territories are established, how they are delineated, the role of hormones, and why neighbors are treated differently than strangers.

### Who Wins?

The resident typically wins interactions with intruders. Researchers cite several reasons why residents win (Maynard Smith and Parker 1976), and no single explanation fits every situation. Animals may use a rule, “residents always win.” However, this explanation has little support, and in most cases, winners of territorial disputes are not based on arbitrary factors (Alcock 2013). Rather, winners often have a physical advantage over their opponents. Residents may hold territories because they have higher resource holding power (RHP). Thus, they are larger or stronger and can outcompete opponents for the space (Huntingford and Turner 1987). However, larger

size does not always determine the winner. Other physiological factors that determine the winner include fat content or some unknown intrinsic trait not necessarily manifested in large size. Indeed, age and experience may influence outcomes, with older individuals more likely to escalate or persist in interactions and thus retain ownership (Alcock 2013).

Residents may value the resources in the territory more than an intruder does because the resident is more familiar with the area, such as where the best food sources are located or the best escape routes to use when a predator attacks, and thus the resident can gain more benefits. Removal experiments using insects, fish, and birds support this idea. When territory owners are removed temporarily, allowing the site to be taken over by a new owner, and then returned later, they often fail to regain the new space if the new owner has occupied the site for some period of time. Indeed, the longer the new owner has occupied the space, the more intense the interactions when the former owner returns, suggesting that the value of the territory to the owner increases as the owner becomes more familiar with the area (Alcock 2013).

### Establishment

Many studies have examined interactions between residents and intruders that occur once an individual already has established a territory. Fewer studies have explored how territories become established initially, particularly in natural settings. Stamps (1988) used field experiments to show that anoles (*Anolis aeneus*) are attracted to conspecifics, presumably using these individuals to signal high quality sites. Individuals then divide up the area, maintaining exclusive use but settling adjacent to each other. This phenomenon, known as conspecific attraction or conspecific cueing, occurs in the broader context of habitat selection and has been applied to conservation practices. For endangered colonial seabirds (e.g., Atlantic puffins, *Fratercula arctica*) and territorial songbirds (e.g., black-capped vireos, *Vireo atricapilla*), researchers used models and song playbacks to lure conspecifics to an area and increase breeding populations.

Related to the idea of conspecific attraction or cueing, prospecting involves nonbreeding individuals moving around and assessing potential breeding sites before eventually settling on one site (Reed et al. 1999). Thus, prospecting refers to establishment of breeding territories only, and animals may use the presence of young as a cue to identify the most suitable territories.

Although one way to establish a territory is to win a fight and evict the previous owner, another set of models for territory establishment incorporates learning. Unlike economic and game theoretical models, which focus on fitness outcomes, learning-based models focus on proximate mechanisms to explain spacing patterns (Stamps and Krishnan 1999, 2001). An individual has positive and negative experiences as it explores an area and interacts repeatedly with conspecifics (Stamps and Krishnan 1999, 2001). Some interactions, such as fights, constitute punishment, which decreases the value or attractiveness of a site and reduces the probability of returning to that area. However, sometimes an individual visits a site and does not interact with a conspecific. During those times, the animal gains benefits from acquiring more information about resources such as food or nest sites within the site, which then increases the value or attractiveness of the site and increases the probability of returning to that site. The outcome in terms of establishing a territory represents the combination of positive and negative feedback from interactions, i.e., persistence and punishment (Sih and Mateo 2001). These models predict that territoriality can arise without aggression. Persistence or low levels of punishment over time and at every encounter, such as chases, by one individual (“nagging”) can make it costly for another individual to use the site. Thus, as long as interactions incur some cost, an animal can secure a territory without aggressive interactions. Observations of birds and anoles support this prediction. Despite repeated attacks from conspecifics, animals return to these areas and eventually gain space (Stamps and Krishnan 2001).

Another way to acquire a territory is to inherit it from one’s parents. In some species, territories are passed down from parents to offspring.

Among cooperative breeders such as Florida scrub jays and Seychelles warblers, as family size increases, helpers expand the boundaries of an existing territory and eventually may bud off their own territory. In red squirrels (*Tamiasciurus hudsonicus*), a mother may leave her current territory and establish another one elsewhere, “bequeathing” the original territory to her daughter.

### Boundaries and Landmarks

Territories represent areas of exclusive use; therefore, they have boundaries. Indeed, such boundaries can be readily apparent to a human observer, as when a gray squirrel (*Sciurus carolinensis*) chasing an intruder suddenly stops at an “invisible” line and turns around, presumably returning to its own territory. One cost of territorial defense, therefore, is maintenance of those borders, which must be patrolled, and occupancy must be advertised to both neighbors and potential intruders. To reduce costs of defense, territorial behavior often occurs in habitats with good visibility or vantage points, which allow residents to detect and repel intruders quickly (Eason and Stamps 1992).

Animals can maintain boundaries and deter intruders using several sensory modalities. Perhaps the best known examples are vocalizations, particularly bird song. Removal experiments with many species indicate that when territory owners appear to vacate an area, the space is quickly filled; however, when researchers play calls mimicking the continued presence of the owner, intruders are repelled (Krebs 1977). Morning choruses of primates (e.g., howler monkeys, *Alouatta* spp.; gibbons, *Hylobates* spp.) and howling by canids (e.g., gray wolves, *Canis lupus*; coyotes, *Canis latrans*) also serve to advertise the presence of territory owners. Boundary marks may be olfactory, e.g., scents deposited on vegetation or other substrates as in ants, salamanders, and mammals. Scent marks convey information about the owner, including sex, age, status, and overall health.

Animals also use visual landmarks to demarcate boundaries, and such boundaries can be natural or artificial, part of the landscape or constructed by the territory owners (Heap et al. 2012). For example, animals can incorporate

pre-existing natural landmarks such as rocks and rivers or human-made features such as roads and fences as boundary markers. They may build paths that intruders rarely cross (e.g., European badgers) or construct mud walls surrounding their territories (e.g., mudskippers, *Boleophthalmus boddarti*) (Heap et al. 2012). Experimental work shows that animals can reduce the amount of time spent in active defense when they use landmarks, because these animals engage in fewer aggressive interactions, and those interactions are shorter in duration (Heap et al. 2012).

Landmarked boundaries can have population-level consequences due to effects on territory size and shape. Territories that incorporate landmarks for boundaries may be smaller due to lower costs of sharing space or larger due to reduced costs of defense or landmarks spaced far apart. Furthermore, boundaries denoted by landmarks may persist longer than those without landmarks. Thus, territory size and shape can influence population abundance and stability (Heap et al. 2012).

### Hormones

As noted earlier, in many territorial species, males maintain exclusive spaces, whereas females occupy undefended home ranges. Such behavior is often associated with levels of testosterone, with territorial behavior appearing seasonally when testosterone levels increase. Increased testosterone levels correlate with increased aggression and sexual behavior. However, they also are associated with suppression of the immune system, reduced parental care, and higher mortality (Wingfield et al. 2001). To determine causal relationships, testosterone levels can be manipulated experimentally using implants. These studies show that increased testosterone promotes territorial behavior, including displays, outside the breeding season when animals typically do not maintain territories. Furthermore, those animals with higher testosterone levels suffered costs associated with enhanced territorial behavior, namely, reduced foraging, increased energy expenditures, and lower survival rates (Marler et al. 1995).

However, testosterone is not always associated with higher aggression and territorial behavior

(e.g., Moser-Purdy et al. 2017a), perhaps because of trade-offs with other performance traits related to fitness. For example, high levels of testosterone may interfere with other reproductive behavior, such as parental care. Other hormones, such as corticosterone, may play a more important role in territorial aggression during certain stages of the breeding season (Moser-Purdy et al. 2017a).

### Neighbor-Stranger Discrimination

Territory owners may become familiar with their neighbors over time. Initially, interactions are intense between neighbors, with frequent displays or fights, until both individuals learn to recognize each other and the boundaries between them. After the initial learning phase, interactions between neighbors decline, and owners may permit neighbors to approach a boundary more closely before engaging them. This reduction in intensity and frequency of interactions has been termed the “dear enemy” effect, and experiments reveal that animals treat neighbors less aggressively than strangers (Temeles 1994). One hypothesis is that neighbors are familiar; individuals learn each other’s identities and respond less aggressively. As a result, they avoid wasting time and energy on known individuals that respect each other’s boundaries. As they learn identities, territory owners are less likely to make mistakes about the neighbor’s role, leading to lower aggression (Ydenberg et al. 1988). However, the effect is strongest when animals maintain all-purpose territories, rather than feeding territories, and it may be due more to relative threats from neighbors versus strangers rather than to differences in familiarity (Temeles 1994). Neighbors represent a lower threat than strangers do because neighbors already possess a territory, whereas strangers potentially can evict the current resident. Furthermore, during the breeding season, neighbors represent competition for mates only, whereas strangers represent competition for both mates and territory.

The dear enemy effect can depend on sex, season, and location within the territory where the intrusion occurs. For example, threats change during the breeding season when females are fertile. At that time, neighbors pose a greater risk because they sire most extrapair offspring. Male

song sparrows (*Melospiza melodia*) exhibit the dear enemy effect, i.e., more aggression toward strangers, before and after the fertile stages, whereas during the stage when females are fertile, males respond as aggressively toward neighbors as they do to strangers (Moser-Purdy et al. 2017b).

Coping with unfamiliar neighbors can be costly. Stephen's kangaroo rats (*Dipodomys stephensi*), an endangered species, suffered high mortality rates when animals were translocated. However, when animals were moved in groups that consisted of familiar neighbors, they experienced higher reproductive success, fewer fights, and increased survival compared to animals moved in groups consisting of unfamiliar individuals (Shier and Swaisgood 2011).

The opposite phenomenon is termed the “nasty neighbor” effect, where owners interact more aggressively with neighbors than they do with strangers. In group living, territorial species, members may fight intensely with neighbors over resources, because neighbors pose a greater threat than strangers do. Strangers represent lower risk due to smaller group sizes, i.e., they are dispersing individuals that travel alone or in smaller groups (Müller and Manser 2007). Indeed, greater aggression toward neighbors versus strangers has been reported in social mammals, cooperatively breeding birds, and social insects (Newey et al. 2010).

## Conclusion

The study of territoriality serves as an excellent example of how application of Tinbergen's questions related to ultimate and proximate approaches can further our understanding of animal behavior. Researchers have modeled, observed, and manipulated ecological factors affecting costs and benefits and thus the degree of territoriality and the size of territories. Researchers have experimentally altered landmarks and hormones to investigate mechanisms of territory maintenance and behavior. Further integration of both approaches will only expand our understanding of territoriality. In addition, the study of territoriality has broader applications. Specifically, conservation biologists can use these concepts to attract more

animals to breeding sites or to increase the likelihood of successful translocations by moving familiar animals together. Some aspects of territoriality, such as interspecific territoriality, have not been well studied to date. Thus, from more basic scientific questions to more applied situations, from building better models to testing those models empirically in the field, the study of territoriality remains full of possibilities.

## Territory

### ► Territoriality

---

## Territory Defense

Deanna Steckler

Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

## Synonyms

Brood defense; Mate-guarding; Territoriality

## Definition

A form of intraspecific competition exhibited by an individual or group to acquire or maintain an area and monopolize resources.

## Introduction

Territorial defense occurs to ensure access to resources and to maximize fitness and reproductive success (Kaufmann 1983). The focal resources vary and can include all or some of food, shelter, mates, and safety. Individuals, breeding pairs, or groups defend territories seasonally or year-round. Territories differ greatly in size and composition. For example, grey wolf (*Canis lupus*) packs occupy areas that range from less than 100 km<sup>2</sup> to greater than 2500 km<sup>2</sup> depending on geographic location, pack size, and prey density (Paquet and Carbyn 2003). They also contain complex topography, multiple prey species, and extensive denning and pup-rearing sites. Alternatively, breeding birds in a high-density nesting colony may only defend the nest that contains their offspring (Kaufmann 1983). Animals may also occupy home ranges at the periphery of their territory (Smith 1985). A home range is an area that animals habitually occupy, but has boundaries too extensive to defend actively. Territories are the centralized location where an animal nests, dens, or otherwise resides (Kaufmann 1983; Smith 1985). While some animals tolerate overlap of home ranges with neighbors, territories are exclusive areas that are protected from intruders. Most territorial defense is intraspecific competition, though, in high-biodiversity environments such as tropical rainforests, territories are also guarded against other species (Losin et al. 2016).

## Sex Differences

Territorial behaviors differ between sexes (Smith 1985). Males maximize fitness by securing sexually receptive females. They will either guard females against other males or protect the food

and habitat resources that attract females. Due to the intensity of male-male competition, it is often the most dominant males that succeed in securing breeding rights to females (Arnold et al. 2011). In group-living species, dominant males spend the most time and energy defending territories when compared to subordinate males or females (Arnold et al. 2011; Paquet and Carbyn 2003). Due to the increased energetic cost to produce offspring, female territorial behavior is centralized around protecting the resources needed to rear young (Smith 1985). In rare instances, females will guard a high-quality male from other females (Fukumori et al. 2009). And, in sex-role-reversed species, males take over parental care of offspring that allows the female to defend territories aggressively.

## Territory Signaling

The specific behaviors exhibited by animals encompass a wide range of sensory perception (Arnold et al. 2011; Herr et al. 2009). Often, animals will combine passive, energetically inexpensive methods of territory defense with physical, active defense. Physically marking the boundaries of a territory is a common, stable, and effective signal to conspecifics. Scent-marking with urine is a common method of distinguishing territories in canids (Arnold et al. 2011; Paquet and Carbyn 2003) and other animals (Herr et al. 2009; Rosell and Sanda 2006). Scent-marking is an energetically cheap method of territory defense because urine is a natural metabolic waste. Some animals will also visually mark territory boundaries by scratching or damaging landmarks such as trees while transferring scent to them. Alternatively, auditory signals such as bird songs are also common behavioral defenses (Tobias and Seddon 2000). Sound travels easily through most environments, and it is more energetically efficient for an animal to call from the center of a territory than to patrol its borders. However, in densely populated areas, males may spend excessive amounts of time calling that they reduce time spent foraging, which can decrease energy intake. It is also important to note that olfactory and auditory signals can alert predators to the

nearby presence of the territory owners and may increase the risk of mortality (Rosell and Sanda 2006). Visual displays are another effective territory defense for animals with small territories and open environments but are often associated with increased cost (Schwartz et al. 2007). For example, some lizard species perform head bob, push-up, and dewlap extension displays. These signal the dominant male's position to other lizards, but increases visibility to predators and is energetically costly. Lastly, if the previously mentioned methods fail, most animals will engage in aggressive, active defense of their territory (Herr et al. 2009; Schwartz et al. 2007; Smith 1985; Tobias and Seddon 2000). This behavior involves chasing intruders out of territory boundaries or fighting. The physical alterations are effective but very energetically expensive and risk injury or death.

## Human Interference on Territorial Defense

Infrastructure development and urbanization can interfere with territorial defense and lead to increased human-wildlife conflict (Herr et al. 2009). For example, urban-adapted stone martens (*Martes foina*) scent-mark their territories with urine during the spring and early summer. In natural environments, urine is deposited on non-mobile objects and is a stable indicator of territory boundary. However, cities contain unstable environments, and scent-marked vehicles move around the environment regularly threatening the integrity of the territory boundary. Male martens increasingly visit, mark, and climb into the engines of cars and cause damage to the components, resulting in conflict with humans. Unfortunately, many territorial signals are outside the realm of human sensory perceptions, so preventing this type of conflict is challenging.

## Conclusion

Territory defense involves a multitude of behaviors intended to establish exclusive dominance over an area and the resources contained within

(Kaufmann 1983). Territorial behaviors vary by species, territory size and composition, sex, season, and resources required. Common defensive signals include olfactory scent-marking (Arnold et al. 2011; Herr et al. 2009; Paquet and Carbyn 2003; Rosell and Sanda 2006), auditory calls and songs (Tobias and Seddon 2000), and visual displays (Schwartz et al. 2007). These methods are used as a strategy to avoid aggression, chasing, and fighting between rivals, which can result in injury or death (Herr et al. 2009; Schwartz et al. 2007; Smith 1985; Tobias and Seddon 2000). Research is demonstrating that human development and infrastructure causes interruptions in territorial signals that can lead to human-wildlife conflict (Herr et al. 2009). However, more research is needed to assess how these interruptions may impact the social communication and ecology of species.

## Terry Maple

Bonnie M. Perdue  
Agnes Scott College, Atlanta, GA, USA

## Background

Dr. Terry L. Maple is an expert in animal behavior and a pioneer in empirically based zoo management. He was born in 1946 in Maywood, California. His academic journey was inspired in part by childhood visits to the San Diego Zoo. He received his Bachelor's degree from the University of the Pacific and his Ph.D. from the University of California, Davis, under the mentorship of Robert Sommer and Gary Mitchell. He directed Zoo Atlanta for 18 years and oversaw its transformation into a world renowned research focused zoological institution. Dr. Maple is trained as a psychologist but integrates perspectives from biology, environmental design, and more. He has advocated for an empirical zoo, with decisions relating to animal care, visitor experience, and exhibit design being driven by scientific research and findings. The depth of his influence on the field is only matched by the breadth of his interests and areas of expertise. Dr. Maple's work ranges from conservation to understanding natural behavior to maximizing animal well-being in captivity.

## Major Contributions

Dr. Maple is an internationally recognized expert on the behavior, welfare, and conservation of great apes, and his ideas regarding the ethological programming in exhibit design have inspired design changes around the world. He has also served an advisory role on optimizing psychological well-being for nonhuman primates in research laboratories and primate research centers. In addition to his work with great apes, Dr. Maple has also served an important diplomatic role with China's efforts on giant panda conservation.

During his tenure at Zoo Atlanta, Dr. Maple also held an academic position at the Georgia Institute of Technology. He retired as the Elizabeth Smithgall Watts Professor Emeritus after 30 years of service in the School of Psychology. Along with his students and collaborators, Dr. Maple has published over 250 journal articles, chapters, and books on the behavior, conservation, and welfare. His work has involved a wide variety of species including African antelopes, baboons, capuchins, chimpanzees, elephants, flamingos, giant pandas, gorillas, giraffe, lemurs, lions, macaques, mandrills, orangutans, reptiles, spider monkeys, tigers, and zoo visitors. He is also the author of many books, including *Ethics on the Ark*, *Zoo Animal Welfare*, and *Professor in the Zoo*.

Dr. Maple is the Founding Editor of the journal *Zoo Biology* published by John Wiley/Blackwell and a founding member of the American Society of Primatologists. He is an elected Fellow of the American Psychological Association, the Association of Psychological Science, and has served as the President of the Association of Zoos and Aquariums.

## Lasting Influence

Throughout his career, Dr. Maple has mentored and opened doors for countless students, colleagues, and collaborators. Those in his academic family continue to serve the zoological community as directors, heads of research programs, and in academic positions around the world. He recently retired as the Director of the Palm Beach Zoo and now works as a consultant on

projects. His influence on the study of animal behavior, in particular in regards to the zoological setting, is monumental and will continue to have long-lasting effects.

## Definition

A testis is a typically paired male reproductive gland that produces sperm and secretes testosterone.

## Introduction

The testis is a component of the male reproductive gland that is responsible for male hormone (testosterone) and male germ cell (spermatozoa) production. It is homologous to the female ovary. Most modern animals have two testis, which may be symmetrical or asymmetrical in size and, if externalized, contained within the scrotum. The anterior pituitary controls the release of testosterone via the release of luteinizing hormone. Sperm production is controlled by the anterior pituitary through follicle-stimulating hormone and gonadal testosterone. In addition to testosterone, the testes also produce the hormones inhibin and estrogen, along with other proteins. The blood-testis barrier makes the testis an immunologically privileged organ, preventing substances from reaching the developing spermatozoa and preventing autoimmune reactions which could destroy developing germ cells. The remainder of this text will discuss basic embryological development, anatomy, function, and species variation of the testes.

## Embryology

During embryologic development, the gonads begin in the intermediate mesoderm adjacent to the kidneys. Initial development of male and female gonads is determined by the testis-determining factor, which is a product of the Y chromosome. Within the developing testes, the three main differentiating cell types include the gamete forming cells (spermatogonia), support cells (sertoli cells), and hormone secreting cells (leydig or interstitial cells). In most vertebrates other than mammals, the testes retain their original position in the abdomen (Farraj et al. 2017). As development progresses in mammals, the sex cord develops within the forming testes and the testes descend from the fetal abdomen to the inguinal ring and beyond to the inguinal canal and into the scrotum in those mammals that have externalized testes. Complete descent of both testis occasionally does not occur, leading to a

condition known as cryptorchidism, where the testis remains internally or stops short somewhere along the inguinal canal.

## Anatomy

The testis is composed of three layers, as well as a meshwork of vasculature and tubules that run throughout. From outermost to inner, these components are the tunica vaginalis, tunica albuginea, and mediastinum. The tunica vaginalis is a thin membrane that provides support and protects the testicle from the peritoneum, or abdomen. Next, the tunica albuginea is connective tissue that provides structure for the testis. The mediastinum is also made up of connective tissue and provides internal support. The seminiferous tubules are a part of the testicular parenchyma, or functional tissue, and are made up of two cell types that produce sperm (germ cells) and substances including androgen binding hormone, transferrin, and inhibin (sertoli or nurse cells). These additional substances produced by the sertoli cells surround developing germ cells and provide structural and metabolic support to the developing spermatogenic cells. Surrounding the seminiferous tubules are the cells that make up the blood-testis barrier.

## Hormone Function and Production

Testosterone is produced under tight control by the hypothalamus-pituitary-gonadal axis (HPG). The hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the release of gonadotropins, luteinizing hormone (LH), and follicle stimulating hormone (FSH) by the pituitary (Hill 2018).

## Variation Amongst Species

There is variation amongst mammals as to whether the testes are internally or externally located. For some land mammals (elephants,

sloths, etc) and cetaceans (whales, dolphins), the testes remain internally within the abdomen (Rommel et al. 2007). Most other land mammals have externalized testes that are located suspended within the scrotum. There are several hypotheses as to why most mammals have externalized testes, with the most widely accepted being the ability to keep the testes at a cooler temperature, which allows for more efficient spermatogenesis and protection against DNA damage of spermatogenic cells (Mills and Marchant-Forde 2010). The relative size of testes is thought to be influenced by mating systems, with those animals that engage in polygamy, typically having larger testes compared to body weight. In many seasonal breeders, the testes may increase in weight during the breeding season (Romer and Parsons 1986).

## Conclusion

While species variation exists in the location and size of the testis, the main function of producing and storing spermatogenic cells is conserved across most species. The testis also produces other hormones and proteins, under the control of the hypothalamus-pituitary-gonadal axis.

**Testosterone, Fig. 1** Molecular structure of testosterone

## Introduction

Testosterone, a steroid hormone, is an important regulator of animal physiology and behavior. Testosterone is secreted from the testis and lesser amount from the ovary. Small amounts of testosterone is also synthesized and secreted from the adrenal gland. Testosterone stimulates the development of male reproductive organs such as testis and prostate, promotes and maintains male secondary sexual characteristics such as growth of muscle, bone, and body hair. Prenatal testosterone secreted from the testis masculinizes the male brain to facilitate male-typical behavior that becomes evident after birth. Temporal testosterone concentration in general circulation at a certain level is also important to maintain male-typical behavior after puberty. Testosterone improves spatial abilities, learning, and memory, and suppresses depression. This section highlights the role of testosterone and its metabolites in cognition and behavior in humans, rodents, as well as teleost fishes to understand their general functions from a comparative standpoint.

## Production of Testosterone and Its Metabolites

Testosterone (Fig. 1), a chemical compound that was first isolated from bull testis by Ernest Laqueur in 1935, is actively synthesized from cholesterol in the Leydig cells in the testis. Synthesis and secretion of testosterone from the testis are ultimately regulated by the hypothalamus-pituitary-gonadal (HPG) axis (Parhar et al. 2016). Adult females contain approximately ten

times lower concentration of testosterone that is produced in ovarian follicle theca cells and the adrenal gland. Testosterone is converted to  $5\alpha$ -dihydrotestosterone (DHT) by the enzyme  $5\alpha$ -reductase in the prostate gland, seminal vesicles, epididymides, and hair follicles. DHT has greater affinity to androgen receptor (AR) than testosterone and acts as the primary androgen in peripheral tissues. Testosterone is also converted to  $17\beta$ -estradiol (E2) by the enzyme aromatase in ovarian granulosa cells, placenta, brain, adipose tissue, blood vessels, skin, and bone. E2 synthesized in the brain modifies human and animal behavior, such as socio-sexual behavior and aggression (Ubuka and Tsutsui 2014).

## Role of Testosterone in Sexual Differentiation of the Brain in Mammals

Testosterone contributes to cell growth, cell migration, synaptic formation, apoptosis, and neurotransmitter synthesis in the brain, which is called organizing effect of steroid action. There is a critical period for masculinization of the male brain, which is thought to be during 8 and 24 weeks of gestation in humans. This organizational action of testosterone is evident in children's toy preference, such as cars for boys and dolls for girls (Hines 2010). Studies in rats have shown that perinatally aromatized androgen (E2) decreases apoptotic activity in the sexual dimorphic nucleus of the preoptic area (SDN-POA) in the brain, which is 2.6 times larger in males than females and important for male copulatory behavior in the adult. The third

interstitial nucleus of the anterior hypothalamus (INAH-3) of humans, which is larger in males than females, is thought to be the homolog of rodent SND-POA (Allen et al. 1989). On the other hand, anteroventral periventricular nucleus (AVPV) that regulates ovulation is larger in females. Prenatally metabolized testosterone enhances apoptosis in AVPV of males and reduces the number of cells compared to females. Posterior dorsal medial amygdala (MePD) that is related to decision making and male sexual arousal is dependent on adult testosterone. MePD is 1.5 times larger in male rats but testosterone manipulation in adults can completely reverse this sex difference.

### **Role of Testosterone in Spatial Abilities, Learning and Memory, and Depression in Humans**

General higher spatial abilities such as mental rotation in men than women suggest the facilitatory role of testosterone on acquisition or maintenance of spatial abilities. Studies have shown that prenatal testosterone, rather than temporal testosterone concentration, has stronger association with special abilities in men and women, suggesting that organizing effect of testosterone is important to facilitate spatial abilities in both sexes (Celec et al. 2015).

Various studies show that testosterone supplementation improves learning and memory in older men and women. It was shown in aged rat that DHT, the nonaromatizable androgen, was not able to improve memory, suggesting that E2 synthesized from testosterone in the brain improves memory. Organizational effect of testosterone on brain structures such as amygdala and hippocampus is also important to facilitate learning and memory after birth.

Because depression is more common in females compared to males and depression in males increases with age when testosterone concentration decreases, testosterone may function as a suppressor of depression. Testosterone concentration is also lower in female depressive patients. It was actually shown that testosterone

supplementation improves depressive symptoms in both men and women, suggesting that temporal testosterone concentration is important to maintain healthy mental condition in both sexes.

### **Androgenic Modulation of Cognition and Behavior of Teleost Fishes**

In teleost fishes, testosterone and 11-ketotestosterone (11-KT), an oxidized form of testosterone, are major androgens in males. Although both testosterone and 11KT act on target cells through AR, evidence suggests that 11-KT, rather than testosterone, plays important roles in the regulation of social behaviors such as sexual and aggressive behaviors in teleost fishes. In male tilapia, plasma 11-KT level is increased in response to courtship interactions. Under male-male interactive conditions, the levels of social hierarchy in male tilapia are positively correlated with peripheral androgen levels. Furthermore, administration of androgen induces male-typical sexual behavior such as chasing and ejaculation act in female teleost fishes, suggesting that sexual differentiation of the brain can be achieved in adults in teleost fishes.

Some fish species can change their sexual phenotypes throughout their lives as a reproductive tactics. In these species, sex steroids including androgens play an important role in gonadal sex changes. Interestingly, in some fish, conversion of behavioral phenotypes can be seen prior to changes in gonadal sexual phenotypes as well as circulating sex steroid levels. Therefore, androgen may not initiate the behavioral change but may be important to convert the brain to display male/female-typical behavioral characteristics such as courtship, spawning, and other behaviors for successful reproduction.

Although the hypothalamus can control behavior by regulating sex steroid production through the HPG axis, several neuropeptides in the hypothalamus are directly involved in the regulation of social and reproductive behaviors (Parhar et al. 2016). Gonadotropin-releasing hormone (GnRH, also known as luteinizing-hormone releasing hormone) is a master regulator of

vertebrate reproduction, which controls the release of gonadotropins from the anterior pituitary gland. In tilapia, there are three types of GnRH: GnRH1, GnRH2, and GnRH3 (Parhar et al. 1996). GnRH1-expressing neurons lie in the preoptic area, which project to the pituitary and are mainly involved in the control of gonadotropin release. On the other hand, GnRH2 and GnRH3 neurons are present in the midbrain tegmentum and the terminal nerve region, respectively, which mainly play neuromodulatory functions in the regulation of reproductive behavior (Ogawa et al. 2006). Treatment with exogenous testosterone reduces GnRH1 but increases GnRH3 mRNA levels in male tilapia (Soga et al. 1998), suggesting that there is a complex interaction between testosterone and the hypothalamus to regulate reproductive behaviors in teleost fishes.

As AR subtypes distribute widely in the brain of teleost fishes, multiple pathways outside of the HPG axis are possibly involved in androgenic modulation of cognitive functions (Parhar et al. 2016). A neuropeptide called kisspeptin (Kiss1) is predominantly expressed in the zebrafish habenula. In teleosts, the habenula is subdivided into the asymmetric dorsal and symmetric ventral subnuclei, which project to the interpeduncular nucleus and the ventro-anterior corner of the median raphe, respectively. Habenular kisspeptin neurons are involved in serotonergic modulation of olfactory cue-induced fear response (Ogawa et al. 2014). Although AR is expressed in the fish habenula, habenular kiss1 neurons are more sensitive to estrogen than androgen (Wang et al. 2013).

## Conclusion

Testosterone is secreted from the testis and lesser amount from the ovary and the adrenal gland. Testosterone is converted to DHT and E2 in mammals and 11-KT in teleost fishes in target organs, and these metabolites further modify the physiology and behavior of the animal by acting in target tissues and the brain. Testosterone has a significant role in sexual differentiation of the male brain in mammals. However, prenatally or

perinatally aromatized E2 may actually masculinize the fetal male brain. This organizational action of testosterone is evident in children's toy preference. Testosterone or E2 also has significant roles in spatial abilities, learning and memory, and suppression of depression in humans. 11-KT plays important roles in the regulation of social behaviors such as sexual and aggressive behaviors in teleost fishes. In contrast to mammals, sexual differentiation of the brain can be achieved by temporal sex steroids in adults in teleost fishes. Hypothalamic and extra-hypothalamic neuropeptides such as GnRH and kisspeptin can directly regulate behavior in teleost fishes, although their gene expression levels are regulated by sex steroids.

## Testudines Cognition

Anna Wilkinson<sup>1,2</sup> and Ewen Glass<sup>3</sup>

<sup>1</sup>School of Life Sciences, University of Lincoln, Lincoln, UK

<sup>2</sup>Wildlife Research Center, Kyoto University, Kyoto, Japan

<sup>3</sup>Lincoln School of Film and Media, University of Lincoln, Lincoln, UK

Reptiles were long considered to be unintelligent beings, with scientists going so far as to suggest that their cognitive abilities were fundamentally different from that of mammals and birds (e.g., Day et al. 1999). However, recent research has revealed an impressive suite of cognitive abilities in this group (e.g., Kis et al. 2015; Siviter et al. 2017; reviewed by Matsubara et al. 2017). Despite this, the body of work in this area remains small and the group is vastly understudied when compared to other vertebrate classes. This entry will provide a brief review of the current state of knowledge in the field of cognition in testudines.

Today's extant testudines (also known as chelonia) are made up of turtles, tortoises, and terrapins. The group comprises of 327 species (van Dijk et al. 2014) and is characterized by a bony shell which encases the body. Chelonia are particularly informative in the study of the evolution of cognitive abilities as phylogenetic analyses place them as a sister group to the Archosauria (birds and crocodiles; Shaffer et al. 2013). Therefore, comparisons of similarities and differences

in performance on cognitive tasks can provide important insights into the evolution of cognition.

## Visual Perception

There is evidence to suggest that at least some chelonia are highly visual (summarized in Wilkinson and Glass in press). They have good color vision, exhibit color preferences (e.g., Pellitteri-Rosa et al. 2010), and are able to learn to discriminate between colors (Soldati et al. 2017; Davis and Burghardt 2011) and perhaps shapes (Glavaschi and Beaumont 2014). However, as yet, few traditional visual perception experiments have been conducted with this group, and as a result we know little about their perceptual capabilities. The work that *does* exist, however, suggests that it would be a fertile area for future research.

An experiment investigating picture-object recognition in the red-footed tortoise (*Chelonoidis carbonaria*) revealed that they behave towards a picture as if it is the object that it represents (Wilkinson et al. 2013); when, in unreinforced test trials, tortoises were asked to discriminate between a real piece fruit and a photograph of fruit, they performed at chance levels, suggesting that they confused the photographs with the real objects (Wilkinson et al. 2013). They were, however, able to learn to discriminate between the two when differentially reinforced for doing so (Wilkinson et al. 2013), suggesting that they certainly perceive the relation between the photograph and the object that it represents, making them an ideal species for further work using photographic stimuli.

## Spatial Cognition

Spatial cognition is considered adaptive as it allows an animal to move between resources in an efficient manner. This is one of the most understood areas of testudines cognition and much work has examined the impressive navigational feats of sea turtles (see ► “Testudines Navigation” entry for more details). However, efficient

navigation is equally as important on a smaller scale. This area has a long history (see Burghardt 1977 for a full review of the early work in this area); however, recent research has revealed some interesting developments in our understanding.

Studies of spatial cognition in mammals and birds have shown that they are able to use a range of strategies to navigate to a specific goal. This includes the use of a cognitive map, in which the spatial relations between a number of landmarks are used to define the goal. This is considered to be highly adaptive as is it robust against the removal of any individual landmark. This ability is thought to be dependent on the hippocampus, where reptiles are of particular interest as their brain structures differ from those of mammals and birds. Anatomical studies have suggested that similar circuitry and homologous structures, however, do exist between the groups (e.g., Naumann et al. 2015) and it is therefore important to investigate this behaviorally.

Chelonia are able to use a number of strategies to navigate towards a reward. There is evidence that both red-footed tortoises and terrapins (*Pseudemys scripta*; e.g., López et al. 2003) are able to use distal cues to navigate and appear to do so in a cognitive map-like manner (reviewed by Wilkinson and Huber 2012). Terrapins are able to navigate towards the same location irrelevant of starting point (López et al. 2001), and use different strategies depending on cue availability (López et al. 2001). The red-footed tortoise is able to learn to navigate efficiently around a radial arm maze (Wilkinson et al. 2007), requiring the animal to remember which of multiple spatial locations it has already visited in a trial (Mueller-Paul et al. 2012). When animals have access to complex and salient cues, they appear to use these cues in a cognitive map-like manner (Wilkinson et al. 2007). However, when cues are not salient, the tortoises' behavior changes and they exhibit stereotypic response strategies, choosing instead to enter the arm next to the one that they have just left (e.g., Mueller-Paul et al. 2012). This strategy is highly efficient in this particular maze, and the ability to switch between strategies is likely to be adaptive in the natural environment. The use of systematic responses

rules can, when reliable, substantially reduce memory load, while the use of a spatial representation of the environment can allow successful navigation despite changes in the external environment.

There is evidence that these response rules can be generalized across very different contexts (Mueller-Paul et al. 2014). Animals trained to make a spatial discrimination on the touchscreen transferred this response rule to a real life arena. Interestingly, if contingencies (spatial position of reinforcement) in the arena were then reversed, the animals did not transfer the reversal learning to the touchscreen context, but rather approached the side which was previously reinforced in that context. This occurred despite the animals receiving no training on the touchscreen for several months. This suggests that context-specific information is used when available and shows evidence of long-term spatial memory in this species.

More evidence to support use of different cues during navigation comes from recent field studies with translocated terrapins (*Chrysemys picta*). This work has revealed that younger individuals are able to follow paths of adults; however, this ability is not observed in older individuals (Roth and Krochmal 2015. See chapter ► “Testudines Life History” for more details). This suggests that animals of different ages may use different information when navigating, a hypothesis later confirmed with pharmacological tests (Roth and Krochmal 2016). Thus, testudines exhibit a range of complex spatial cognition abilities, the extent of which we are just beginning to investigate.

## Social Cognition

Recent research has revealed evidence of complex social cognition in chelonia. Gaze following is considered highly adaptive as it alerts an individual to important changes in the environment. There is evidence that red-footed tortoises are able to follow the gaze of a conspecific (Wilkinson et al. 2010b). They are more likely to look up if they see a conspecific doing so, than in control trials in which they see an empty arena or a

conspecific that does not look up. Further, there is evidence to suggest that they respond more to cues from a conspecific than those of a hetero-specific or model tortoise (Wilkinson et al. unpublished data). Further work is required to more fully investigate the cognitive underpinnings of this behavior.

Social learning is considered adaptive as it can allow an animal to solve a task without the costly process of trial and error learning (Laland 2004). Davis and Burghardt (2011) have revealed that the terrapin *Pseudemys nelsoni* is able to learn to select a stimulus associated with a reward through stimulus enhancement (see chapter ► “Stimulus and Local Enhancement” for more details of this method). Red-footed tortoises are also able to learn from observing the behavior of a conspecific (Wilkinson et al. 2010a). In a detour task (see chapter ► “Detour Task” for more details of this method), one group of tortoises observed a conspecific making the detour and eating food at the goal, while the other group did not. All animals in the observer group successfully reached the goal, while none of the control animals were able to (Wilkinson et al. 2010). The social learning mechanisms that control this behavior remain unclear; however, later tests revealed that the tortoises did not simply learn to follow the particular route that the demonstrator took, but rather learned some general principles about how to solve the task (Wilkinson and Huber 2012).

Tortoises also serve as an excellent group with which to examine hypotheses related to higher level cognitive processing. The literature has suggested that certain behaviors are related to higher level cognitive processes, but they do not directly test this. Take contagious yawning as an example; three hypotheses have attempted to explain this phenomenon. It has long been thought that contagious yawning is the result of empathy, which is cognitively complex and requires mental state attribution (e.g., Anderson et al. 2004). However, another hypothesis suggests that the phenomenon may result from non-conscious mimicry, which can emerge as a result of links between perception and action (Yoon and Tennie 2010). However, contagious yawning may also be the result of a fixed action pattern, the

releaser stimulus being the observation of a yawn (Yoon and Tennie 2010). Tortoises are ideal for investigating such questions as they are able to use social cues, but there is no evidence of social mimicry, mental state attribution, or empathy in this species. The results revealed no evidence of contagious yawning in this species, suggesting that this behavior may indeed result from higher level cognitive processes (Wilkinson et al. 2011).

## Long-Term Memory

Long-term memory is considered adaptive as it allows an animal to retain information about valuable resources. Red-footed tortoises can remember a spatial discrimination on a touchscreen for 3 months (Mueller-Paul et al. 2014). However, recent research has revealed that they are able to retain information about the relative reward value of a stimulus for at least 18 months (Soldati et al. 2017). Tortoises were trained to associate colored stimuli with different reward qualities and quantities (favored vs. less favored; more vs. less). They learned the association and worked harder for the preferred rewards; they were then given a retention interval of 18 months before being tested on the same discrimination. The results revealed that the tortoises retained information about stimuli associated with the relative value of both reward types. This is likely to impact upon foraging decisions in the natural habitats (John et al. 2016). Other work with *Pseudemys nelsoni* has revealed that they are likely to be able to remember how to perform a food acquisition behavior after a retention period of 36 months (Davis and Burghardt 2007, 2012) and can retain a visual discrimination after 3.5 months of nonexposure (Davis and Burghardt 2012). Taken together, these findings reveal impressive evidence of long-term memory in a suite of cognitive domains.

## Summary

Though still in its infancy, the growing field of testudines cognition has already yielded

impressive results, which gives impetus for more widespread study. These data can, when compared with data from other groups, provide crucial information about the evolution of cognitive abilities. Our increased understanding of cognition in this group also has important considerations for their captive care, with greater cognitive abilities comes greater capacity to suffer (Moszuti et al. 2017), as such, these advances are essential for our understanding of welfare in this group.

## Definition

Summary of cognitive abilities of and processes in turtles and tortoises viewed in light of life history traits

## Introduction

Turtles and tortoises have been the frequent subjects of field studies. Decades of natural and life history study have provided us with a deep knowledge of the basic biology of this diverse group in an ecological and evolutionary context. Despite this work, there is a relative paucity of work on behavior and cognition in the Testudines, particularly in naturalistic environments. Based on their phylogenetic position, assumptions rooted in culture, aspects of gross neuroanatomy, and misinterpretations of the nature of their behavior, turtles have historically been considered to lack complex cognitive and behavioral abilities (Wilkinson and Glass [in press](#)).

Laboratory work has, however, provided strong support for an array of cognitive abilities among turtles and tortoises, supporting the notion that they possess greater cognitive abilities than once considered possible. These abilities include, but are not limited to, complex spatial memory, social cognition, fine discrimination/preference ability, and personality (Wilkinson and Huber [2012](#)). While informative, these studies often lack developmental, ecological, and evolutionary perspectives for the aspects of cognition demonstrated therein. As a result, our understanding of the cognitive abilities of turtles and tortoises is incomplete. Designing studies that investigate cognition within the framework of the animal's life history can work to fill this knowledge gap and to enhance the understanding of turtle and tortoise cognition and behavior. Integrating behavior, cognition, and their underlying mechanisms with life history at the individual, population, and community level will provide a more complete and relevant context in which to interpret experimental findings and provide motivation for the work (Angeloni et al. [2010](#)). For example, a *gestalt* understanding of the proximate cognitive

factors that influence behaviors within a life history setting can inform behavioral studies by giving researcher the ability to more appropriately motivate animals and thereby enhance the design of behavioral experiments. Additionally, life history explicitly considers the selective pressures that shape behaviors, thereby identifying the factors relevant to the evolution and maintenance of such behaviors. These emergent properties of behavior may not be immediately apparent in the controlled and stable settings of the lab in which many behavioral studies occur. Thus, the study of life history provides the framework to better understand how animals respond behaviorally to dynamic environments and how such interactions scale up to influence large-scale phenomena. Ultimately, this might translate to enhanced understanding of the evolution of cognition (Greggor et al. 2014; Roth and Krochmal 2015a).

### **Cognition Through the Lens of Life History**

Classically, ecologists define life history as the timing of key events of a species across the life span of the organism as shaped by natural and sexual selection (Bonin et al. 2006). Life history studies traditionally include the timing, size, and size of reproductive efforts, life span, and key developmental and growth patterns. While some aspects of life history may be associated with cognitive ability, studying life history alone does not fully provide the ecological and evolutionary context discussed above. Therefore, this chapter embraces a more broad definition of life history that includes the elements of natural history, specifically interactions with the social and physical environments.

Embracing this broad life history perspective provides the backdrop for a deeper understanding of turtle and tortoise behavior and cognition. Knowing species-specific ontogenetic patterns can reveal the costs and benefits of learning across development. Understanding patterns of habitat and space use in turtles and tortoises highlights the roles of cognitive processes in respond to changing environmental conditions across a

range of temporal and spatial scales. Natural environmental stressors provide strong selection pressures for complex cognition and rapid learning. Likewise, examining the social environment of turtles and tortoises provides the opportunity to reveal more complex social cognitive processes. Finally, examining how these taxa are both prey and predators in the field reveals a broad suite of cognitive capabilities from perception to shifts in preferences and decision-making under different contexts.

### **Development and Ontogeny**

Turtles and tortoises exhibit a slow life history strategy typified by a relatively long life span and delayed onset maturity (Bonin et al. 2006). Examining cognition within the species-specific age structure of turtles and tortoises provides an understanding of the patterns of learning over development. Being relatively long lived, turtles and tortoises are more likely to encounter a variety of environmental conditions and changes therein throughout life. Thus, the ability to learn about those conditions and to respond to such changes cognitively is potentially adaptive (Urban et al. 2014).

As a function of being relatively long lived, turtles and tortoises have a delayed onset to maturity. Typical of this life history strategy, they show highly characterized patterns of learning during development, often occurring within a specific time window, e.g., a critical learning period. A critical period represents a trade-off between the benefits of neural flexibility and the costs of maintaining that flexibility, costs that might be prohibitively high across a long life span. In an ontogenetic study of navigation, Roth and Krochmal (2015b) found evidence of age-specific learning about upland habitat in painted turtles. The authors revealed that learning about habitat is governed by a critical period ending at age 3 years. Similarly, juvenile loggerhead sea turtles learn the geomagnetic coordinates of their natal beach and recall that information when returning as adults (Lohmann et al. 2001). In both of these cases, learning complex habitat in early

development can be beneficial as it reduces the costs of maintaining plasticity.

### Spatial Use and Habitat Choice

Turtle and tortoise species vary greatly in their space use of their territories, home ranges, and/or across migratory movements. Sea turtles can traverse large portions of the Atlantic Ocean within a single year, whereas a box turtle might use but a few hundred square meters throughout its entire life. All else equal, animals that use more space within a territory or home range often have increased spatial cognition (e.g., spatial memory) capabilities and higher general cognitive capacities and enhance in the mechanistic underpinnings (e.g., neural processing) that support cognition.

Patterns of space use among turtles and tortoises can illuminate the cognitive mechanisms behind such complex behaviors as navigation. Many turtles and tortoises respond to changes in environmental conditions at a landscape level by using a cognitive approach. As behavior is a means by which animals can respond to rapid changes in the environment, changes that occur more rapidly than evolution would otherwise be able to accommodate physiologically (Greggor et al. 2014). Like many other taxa (e.g., birds and mammals), turtles and tortoises can migrate in response to seasonal changes in habitat quality or between reproductive and foraging areas across different life stages. For example, Roth and Krochmal (2016) demonstrated that painted turtles learn to navigate complex migratory routes through terrestrial habitat via spatial memory when faced with seasonal habitat loss. This phenomenon also occurs at larger temporal and spatial scales, with sea turtles learning and recalling specific geomagnetic cues to facilitate long-distance travel across the Atlantic Ocean between breeding, nesting, and feeding areas.

### Habitat Use and Abiotic Factors

Many turtles and tortoises experience extreme abiotic conditions, and those abiotic factors can often act as strong selection pressures and thus strong motivators. Understanding patterns of habitat use can demonstrate turtle and tortoise discrimination among and preferences for specific

aspects of the environment. The selection of habitat for feeding, basking, and nesting sites provides detailed evidence that these taxa possess fine habitat discrimination ability in highly heterogeneous environments. Moreover, this work had provided the backdrop by which to study the development of these decision patterns and abilities. For example, Tamplin (2009) demonstrated that some species of turtle have age-specific thermal discrimination. Three-month-old wood turtles lack the ability to discriminate temperatures and thus fail to select warmer temperatures.

Identifying and selecting appropriate habitat patches can have important consequences for fitness. Natural selection, should then, promote the ability to rapidly dissociate suitable from unsuitable habitat types. For example, gopher tortoises have very specific criteria that they use to select burrows, and the criteria on which they base the decision are plastic as a function of habitat (Lau and Dodd 2015). Furthermore, studying the discrimination of habitat qualities in field conditions provides us the opportunity to understand how turtles and tortoises respond to fluctuations in habitat quality and suitability. Refsnider and Janzen (2012) show that painted turtles' discrimination among nest sites as a function of thermal characteristics becomes finer in rapidly changing environments. This behavioral plasticity in nest site selection can then provide a buffer against the negative effects of climate change (Refsnider and Janzen 2012).

Evidence from conservation studies can also benefit our understanding of turtle and tortoise cognitive abilities. Researchers are beginning to appreciate the relevance of incorporating a cognitive or behavioral mind-set into such strategies (Blumstein and Fernandez-Juricic 2010). For example, translocation is a common conservation tool used to bolster population size by moving individuals among different population. Providing turtles and tortoises with additional time and safeguards to learn novel systems during translocation might be sufficient to promote long-term relocation success in some species (Bauder et al. 2014). Moreover, the process of translocation can be helpful as a tool itself to experimentally observe animals in novel situations to better

understand how they learn and interact with novel habitats (Krochmal et al. 2018). Translocated box turtles, for example, move farther distances and have significantly larger home ranges relative to resident animals, suggesting that they exhibit context-specific patterns in movement behavior (Hester et al. 2008).

### Social Structure

Historically, herpetologists have not considered turtles and tortoises to be social organisms. Although communal behavior is common among Testudines, traditional ecological research in the field has documented little direct interaction between individuals outside of breeding. Documenting and quantifying sociality in infrequently studied systems like turtles and tortoises is predicated on an increasing reliance on strong inference, is often subject to an elevated burden of evidence, and requires the rejection of additional alternative hypotheses. Despite these challenges in the field as a whole, investigating sociality in turtles and tortoises has provided us an opportunity to reconsider our understanding of what it means to be social and moreover the evolutionary origins of social behaviors (Doody et al. 2013). Assessing sociality in turtles and tortoises provides insight and context to studies of the evolution of social cognition and comparative psychology, insight only gained by adding a broad phylogenetic perspective.

Examining the potential for social behavior in the field from this new perspective has provided some evidence that sociality in some lineages of turtles and tortoises is more complex than previously assumed. For example, desert and gopher tortoise maintain and defend burrows and aggregate in nonrandom social networks (Radzio et al. 2016; Sah et al. 2016). Some species of river turtles vocalize underwater with offspring, potentially representing a form of parental care (Ferrara et al. 2013). Moreover, there is some evidence for conspecific communication and coordination of hatching during development (Doody et al. 2013). This field work supports a wealth of lab-based investigations also demonstrating complex social structures and advanced social cognition in some turtle and tortoise taxa (Wilkinson and Huber 2012).

### Predator/Prey Interactions

Predation is arguably the single most important factor shaping an animal's ecology (Lima and Dill 1990). The response to predation then has implications for nearly all aspects of behavior and can potentially shape proximate and ultimate aspects of cognition. Thus, the range of ways in which turtles and tortoises respond to the risk of predation can give unique, ecologically relevant insight into their potential range of cognitive abilities.

Turtles and tortoises respond to predation risk in a variety of ways, some of which potentially have cognitive underpinnings. For example, they can learn to ignore a perceived predation risk and can become more bold under certain conditions. Pond turtles that live in areas frequented by humans habituate to their presence and learn that humans do not represent a predation risk (Polich and Barazowski 2016). Likewise, some turtles exhibit state-dependent behaviors relative to predation risk. In the face of varying predation risk, green sea turtles decide to spend more time in risky habitats when in poor body condition but prefer safety when in good condition (Heithaus et al. 2007). Similarly, freshwater turtles alter nesting behavior according to a balance of trade-offs of current (risk to self) and future (risk to offspring) fitness (Spencer 2002).

Thinking about turtles and tortoises as predators exemplifies the varied cognitive processes underlying such behaviors as foraging and prey selection. Food items included in the diet can be flexible based on availability in the environment (Luiselli et al. 2004). In contrast, prey preferences in some species can be learned in early development and expressed throughout life. For example, common snapping turtles learn food preferences as juvenile that can become fixed (Burghardt and Hess 1966). Moreover, preferences can be contextually based. Exploratory foraging behavior in hawksbills can lead to adaptive shifts in dietary preferences (Wood et al. 2017). Similarly, sea turtles demonstrate species-specific color aversions to prey items in the lab, though these preferences do not manifest under natural feeding conditions (Swimmer et al. 2005). This work highlights the importance of considering context-specific flexibility of species diet as well

as the importance of investigating complex behaviors in the field.

## Conclusions

Investigating cognition in light of natural history likely requires working under field conditions. This approach has its challenges, but these challenges also offer unique viewpoints into cognition that would be otherwise unavailable. Working in the field often imposes limitations on the extent that researchers can control the observational or experimental environment (e.g., temperature, moisture) and the state, condition, and experience of the individuals included in the study. Though these conditions immediately may seem detrimental to research, they in fact are empirical strengths, offering a more naturalistic view of the focal behaviors and the animal's interaction with their environment. This can be a great strength to the study of cognition. Unlike in laboratory studies, working in the field does not require researchers to train animals in a particular task, as they are already "trained" by natural selection. Further, laboratory studies of cognition frequently utilize repeated measures designs. However, detailed and repeated observation of individuals in the field can be difficult to achieve as recapture or resightings may not be predictable. Instead, researchers can overcome these limitations by using a between-subject design and harnessing the larger number of animals generally present at the population level. Finally, field-based phenomena occur across temporal and spatial scales far larger than are found in laboratory study. Such time and spatial scales can, however, highlight the role of cognition in the manifestation of large-scale behavioral phenomena at the level of the individual, the population, and the community. For example, field work can provide insight into the ontogeny of cognitive processes in species, the influence of cognition in multi-species interactions, local adaptation, and cultural/social learning.

Assessing cognition in light of life history provides insight and context to behavior, cognition, and comparative psychology gained only by

adding the broad perspectives inherent in the study of ecology and evolution. Studying turtles and tortoises in this context provides the opportunity to examine this group of animals, allowing for the integration of their basic biology and cognitive abilities in a new light. Moreover, this approach allows researchers the ability to generate specific, testable hypotheses to further the study of cognition in the future. Such studies also potentially inform applied disciplines including animal welfare, captive animal management, and conservation providing a more comprehensive understanding of turtle and tortoise cognitive abilities.

### What Are the “Testudines”?

Testudines (also known as chelonians) is an order composed of about 300 reptile species popularly known as turtles, tortoises, and terrapins that can occupy a wide variety of ecological niches, from marine and freshwater to terrestrial environments (Uetz et al. 2019; Ernst and Barbour 1989; Fig. 1).

Such animals exhibit a combination of ancestral and extremely specialized features that are exclusive to the individuals belonging to this order (Pough et al. 2018). Distinctive chelonian characteristics are the presence of a shell composed by the carapace (upper part of the shell; Fig. 2a), plastron (lower part of the shell; Fig. 2b), and the location of the shoulder girdle within the rib cage. Such characters are well developed even in the earliest known turtles (Renous et al. 2008).

The chelonian skull is a highly modified structure: typically rather broad and flat and greatly expanded behind the eye area but with a short and narrow facial region (Fig. 3). Additionally, the skull is akinetic, i.e., it does not present any area where the bones articulate (=move) among themselves; the pterygoids (bones associated to the upper part of the skull) are solidly fused to the braincase, and the highly developed and peculiar quadrate is tightly bound to a great lateral expansion of the optic capsule. The temporal roof does not present any opening (also known as fenestra) but is generally emarginated from behind or below or both. Teeth are lost and have been replaced functionally by a horny bill (Romer 1956).

The vertebral number is nearly invariable in chelonians, with all living turtles having eight cervical vertebrae. Cervical ribs (when present) are rudimentary and confined to the posteriormost vertebrae. The trunk has ten dorsal vertebrae with the first and last attached but not fused to the carapace and the middle eight firmly fused or co-ossified with the neural bones of the carapace. The two sacral vertebrae link the pelvic girdle to the vertebral column by short and stout ribs. The caudal vertebrae number is variable but usually less than 24 in most species. The trunk ribs extend outward and fuse with the costal bones of the outer shell. Both elongation and shortening of the neck vertebrae result in distinct neck lengths among chelonians (Vitt and Caldwell 2009).

As in other reptiles, the divisions of the dorsal and ventral group of trunk muscles (epaxial and hypaxial) are not evident and are reduced to fit organs within the shell. In contrast, appendicular, head, and neck muscles are extremely well developed (Vitt and Caldwell 2009; Kardong 2014). The limb structure of turtles is highly variable, reflecting the environment and locomotory modes of the species (Fig. 4). For instance, marine species and the freshwater *Carettochelys* have well-developed flippers with extremely elongated digits that do not move independently (Fig. 4a). Most aquatic species have well-developed webbing between the digits, which

**Testudines Morphology, Fig. 1** Examples of the morphological diversity in Testudines: Terrapins (a–d), tortoises (e, f) and turtles (g). Figures (a–e): Roberto Murta/Bicho do Mato; Figure (f): Camila Mattedi

still retain some independent mobility (Fig. 4b). Terrestrial chelonians (i.e., tortoises) usually have stout limbs capable of lifting their heavy bodies off the substrate but are obviously ineffective for swimming (Fig. 4c). Their digits are usually reduced, and the feet are equipped with thick pads (Pough et al. 2004).

Additionally, the Testudines share a series of characteristics with several fossil groups, such as a distinctive ear region wherein the eardrum is supported by the squamosal (rather than by the quadrate) and by the retroarticular process, a backward projection of the lower jaw. Further, the foot is unique in the way the digits articulate with the ankle bones (Kardong 2014). Although there has been a wide debate on the origin of the modified anapsid skull, its features associated to the shell and post-cranial skeleton are unique among all known vertebrates (Pough et al. 2018).

## Cryptodira X Pleurodira

Extant chelonians belong to two lineages, which are mainly distinct in relation to the mode of neck retraction into the carapace: Cryptodira and Pleurodira (Herrel et al. 2008). Cryptodira represents the most diverse group of hidden-neck turtles found throughout the temperate and tropical regions of the world (Moustakas-Verho et al. 2017), exhibiting an S-neck retraction (vertical plane) inside the shell. Pleurodirans are known as side-necked turtles, with a lateral retraction (horizontal plane), with distribution occurring mostly along the Southern Hemisphere (Herrel et al. 2008; Moustakas-Verho et al. 2017). Pleurodires have a specialized cervical vertebrae (CV) anatomy with the CV5-CV6 articulation being the major point of flexure in neck retraction what reflects a key point for the evolution of Pleurodira (Mariani and Romano 2015). This specialization guarantees them a longer neck, improving performance in the capture of mobile food in the water (Herrel et al. 2008).

In addition to differences in the neck, cryptodires possess an ancestral musculoskeletal morphology, with most hip muscles originating on the pelvic girdle. In these species, the pelvic girdle is not fused to the shell. In contrast, pleurodires exhibit a derived morphology, in which fusion of the pelvic girdle to the shell is present and has resulted in shifts in the origin of most hip muscles onto the interior of the shell (Mayerl et al. 2017). Moreover, skulls may vary in size and shape, mostly regarding their jaw architecture and musculature, with pleurodires

**Testudines Morphology, Fig. 4** Examples of different limb structures exhibited by Testudines. (a) Sea turtle flipper in adaptation to strictly marine environments; (b) terrapin flipper exhibiting webbing between digits in

adaptation to aquatic environments but capable of climbing in river rocks; (c) stout limb of a tortoise, in adaptation to terrestrial environment

usually exhibiting flatter and broader skulls. Such an architecture might have allowed the evolution of gape-and-suck mode of feeding, which is present in several South American species such as the matamata (*Chelus fimbriatus*).

## The Turtle Shell

The body of extant turtles is well known because of their distinct shape in relation to other tetrapods. It is composed by their shell, which is variously modified to provide protection from predators, shelter from the environment, enhance thermoregulation, and act as a rich reservoir of fats, minerals, and water. By enabling extensive concealment of extremities, shell-closing systems deter potential predators and promote survival both on land and in shallow water (Nagashima et al. 2012; Cordero 2017; Cordero et al. 2018). While the tortoise shells are very often high and domed – possibly as an adaptation to hamper predation – aquatic turtles usually bear streamlined shells (mostly for swimmers), although some shells may be less streamlined often with ridge carapaces to assist camouflage (mostly for species that are bottom-walkers).

The turtle bony armor has apparently originated independently many times in reptilian evolution, but the chelonian type of armor has appeared only once (Zug 1971), with this turtle-specific

arrangement having persisted over the last 210 million years (Lyson and Joyce 2012). However, the turtle shell is an evolutionary innovation that has been a mystery for evolutionary biology (Ferreira 2016), with its homologies being debated since at least the nineteenth century (Moustakas-Verho et al. 2017). Many biologists have for long claimed that the turtle shell takes shape from skin cells adjacent to the ribs that are transformed into bone in the course of development. However, Japanese developmental biologists have recently suggested that the shell is most likely a direct outgrowth of bones themselves (Lubick 2013). Additionally, extraordinary fossil discoveries indicate that terrestrial early turtle-like reptiles exhibit transitional features that eventually gave rise to the fully shelled *Proganochelys*. Turtle-like fossils, such as *Eunotosaurus* (260 million years old), *Pappochelys* (240 million years old) and *Odontochelys* (220 million years old) suggest that the ventral shell elements evolved first, followed by broadened ribs that eventually gave rise to the fully hardened dorsal shell. This has recently led to the intriguing hypothesis that the incipient shell might have evolved as an adaptation to life underground, rather than, as traditionally thought, an anti-predator defense. Moreover, other distinctive turtle skull and limb traits were distinct in these fossils (Cordero 2017).

The carapace is formed from costal bones fused with ribs, neural bones fused with

thoracic vertebrae, peripheral bones, and an anterior nuchal bone, covered by keratinized epidermal shields (Burke 1989; Moustakas-Verho et al. 2017). Developmental evidence and muscular attachments suggest that the nuchal bone is derived from the cleithra of the ancestral tetrapod pectoral girdle (Gilbert et al. 2001).

The plastron is the order-defining skeletal structure for turtles (Rice et al. 2016) formed from the suturing together of an entoplastron (interclavicle), epiplastra (clavicles), and three to five paired bones (Moustakas-Verho et al. 2017). The absence of the ventral portion of the ribs and the sternum suggests that plastron assumed their role (Rice et al. 2016). There are a few hypotheses the plastral bones of turtles and the gastralia of other tetrapods are homologous (Gilbert et al. 2001), but such suggestion has still been a debate over the years.

The dorsal and ventral armor are covered by a keratinized epithelium, and two epithelial appendages might be present in the turtle shell: scutes (large epidermal shields separated by furrows and forming a unique mosaic) and tubercles (numerous small epidermal bumps located on the carapaces of some species). Recent studies have suggested the scute of the turtle shell as an evolutionary novelty, whereas tubercles are homologous to reptilian scales (Moustakas-Verho and Cherepanov 2015).

Although the body structure is the same in all individuals, the shell morphology varies according to habits of each species (e.g., flat shells are more hydrodynamic, which may justify their presence in aquatic turtles). In addition, the interspecific shape variation in terrestrial turtles is greater than in aquatic species (Claude et al. 2003). This type of variability can be explained by the complexity of the adaptive landscape in terrestrial environments in relation to aquatic ones, providing multiple niches (Schluter 1986). Additionally, turtle species can often be recognized by the tessellation and pigmentation of scutes on their shell, and scutes have been independently lost or reduced in certain freshwater and marine taxa (Moustakas-Verho et al. 2017).

## Modifications and Adaptations to an Enclosed Body

Diversification of the turtle shell comprises remarkable phenotypic transformations, mostly regarding their internal visceral organization, locomotor apparatus, neck region, and copulatory mechanism (Cordero et al. 2018). For instance, internal muscle connections and limb articulations were modified during the repeated evolution of shell kinesis in small-bodied terrestrial or semiaquatic turtles, as well as modifications of the limbs in terrestrial species (tortoises). Also, change in the muscles that enable lung function was necessary to accommodate early steps in the evolution of the shell.

The location of the heart varies within reptilian lineages and even within taxa, although the heart tends to be positioned roughly along the axial midline. In chelonians, part of the heart is often deep to margins of the humeral and pectoral scutes; however, in some species, it is positioned more posteriorly along the midline between humeral-pectoral and pectoral-abdominal scute lines. The heart was repositioned during the evolution of soft-shell turtles, being relatively displaced to the right, and typically just caudal to the level of the acromion processes and cranial to the distal procoracoid process – procoracoid cartilage junction (Wyneken 2009; Cordero 2017).

Changes in the muscles that enable lung function were also necessary to accommodate early steps in the evolution of the shell. As most tetrapods inhale by ribs expansion (aided by muscle functions), incorporation of the ribs into the turtle shell negates the costal movements that effect lung ventilation in other air-breathing amniotes. Recent studies have indicated that the early stem lineage of turtles deviated from the basal amniote body plan (in which locomotion and breathing are coupled) and evolved a division of function in which the ribs took on a stabilizing role, whereas the abdominal muscles became specialized to ventilate the lungs. Instead, turtles have a unique abdominal muscle-based ventilatory apparatus which most likely evolved through a division of labor between the ribs and muscles of the trunk in which the abdominal muscles took on the primary ventilatory function, whereas the broadened

ribs became the primary means of stabilizing the trunk. These changes occurred approximately 50 million years before the evolution of the fully ossified shell (Lyson et al. 2014).

The independent evolution of the carapace and plastron also required several musculoskeletal changes such as muscle modification, shortening of the trunk, widening of the ribs, encapsulation of the ventral scapula into the chest, loss of intercostal muscles, and reorganization of the respiratory muscles (Rice et al. 2016). For instance, internal muscle connections and limb articulations were modified during the repeated evolution of shell kinesis in small-bodied terrestrial or semiaquatic turtles. Moreover, the evolution of jumbo-sized shells was accompanied by modifications of the limbs in terrestrial species (Cordero 2017). Additional particular characteristic of the chelonians is the location of the girdles within the rib cage. The pectoral girdle is composed of a long scapula, an acromion process, and a coracoid process differing them to the other tetrapods (Renous et al. 2008).

## Conclusion

Chelonians have evolved a novel generalized structural body plan with unique functional mechanisms which guaranteed their evolutionary success along about 220 million of years. The turtle shell provides defense, shelter, and physiological balance, and their distinct enclosed body has resulted in several modifications in the axial skeleton, appendages and appendicular muscles, as well as visceral topography. Even though several issues regarding chelonians evolutionary history are still under debate, this group has carried specialization a long way and without doubt to the greatest extreme of any of the chordates.

## Synonyms

[Chelonia navigation](#)

## Introduction

The order Testudines comprises several species of turtles, terrapins, and tortoises. They are found in a variety of ecosystems occurring in temperate and tropical regions and can be terrestrial, freshwater, or marine (Savage and Gaffney 2015). They are also known to migrate seasonally between habitats, whether for feeding, nesting, hibernating, or estivating (Iverson et al. 2009). Aquatic, semiaquatic, and terrestrial species migrate relatively short distances (between 1 and 27 km) between habitats. Marine turtles, however, have the longest migration of any reptile, migrating thousands of kilometers in their lifetime between feeding locations and breeding grounds. There are several mechanisms used by members of the order Testudines for navigation between habitats from hatchling stage into adulthood. Orientation and navigational mechanisms include a geomagnetic compass, various visual cues, and inertial, slope, or olfactory cues. The navigational mechanisms used by organisms belonging to the order Testudines vary across species and over life stages and may be used separately or in conjunction with each other. Of all the members of the order Testudines, the sea turtles are the most extensively studied (reviewed in Southwood and Avens 2010).

## Geomagnetic Map Navigation

If an animal is able to detect the earth's magnetic field, they must be able to detect at least two features in order to determine their position. The first is the angle of inclination and the second is field intensity, which form a grid across the surface of the earth. The grid, or bicoordinate map, helps turtles to determine their position on the globe (Lohmann and Lohmann 1996). The intensity can refer to the total intensity of the field, the vertical intensity, or the horizontal intensity (Lohmann et al. 2008). However, it should not be assumed that all animals utilize the earth's magnetic field in the same way. Some animals may be able to use one feature to determine their position in one direction relative to a goal (Lohmann et al. 2008).

Complications in the use of a geomagnetic map are due to secular variation, which refers to the gradual change in features of earth's magnetic field over time. Changes do not occur in a stable manner worldwide, but rather changes occur at different rates, in different locations, and different times. To compensate for this, an organism that stays within a region for a duration of time will incorporate the changes in magnetic field into their learned geomagnetic map. If the organism does not learn the changes, then other mechanisms of navigation must be employed (Lohmann et al. 2008).

To explain the usage of a geomagnetic map in members of the order Testudines, the ferromagnetic hypothesis has been proposed. This hypothesis states that an animal has specialized organ structures containing nanoparticles which form chains in the presence of a magnetic field. The nanoparticles can be single domain or superparamagnetic. Single domain nanoparticles have a magnetic moment that remains stable over time and temperature changes (Belova and Acosta-Avalos 2015). These particles have the ability to align with the earth's magnetic field and may have the possibility to send magnetic signals to the nervous system. Superparamagnetic particles do not have a magnetic moment without a magnetic field present. In the presence of a magnetic field, the particles will develop a magnetic moment that tracks the external field but does not align with the field. They can produce a magnetic field strong enough to attract or repel nearby particles, which can in turn stretch or contract a cellular membrane. The expansion or contraction of a membrane may convey messages to the nervous system. Magnetite is a nanoparticle that can be either single domain or superparamagnetic, depending on the size of the particle (Johnsen and Lohmann 2005). Magnetite has been extracted from the heads of sea turtles and several other animals known to orient magnetically, suggesting the use of magnetite in magnetoreception (Perry et al. 1985).

## Visual Cues

The sun can be used as a compass cue for members of the order Testudines, as it can provide directional information when referenced to the

earth's horizon (reviewed in Southwood and Avens 2010). In order to orient using a sun compass, the organism must be able to calibrate their internal biological clock to changes in the sun's azimuth, which is approximately 15° per hour. Sun compass orientation can be demonstrated by exposing an organism to an experimentally altered photoperiod and then allowing it to orient. For example, when exposing an organism to an artificial photoperiod that delays the sun's rise by 6 h, the animal should exhibit a shift in orientation by 90° (DeRosa and Taylor 1982).

The sun compass may be used alone or in conjunction with polarized light cues. Light polarization occurs as sun rays are scattered by molecules in the atmosphere (reviewed in Southwood and Avens 2010). Polarization can also occur as light is reflected off of water surfaces (Mathger et al. 2011) or in water as deep as 200 m. Skylight polarization is fixed, with the highest amount of polarization occurring on the axis 90° to the sun's position along its azimuth and the least amount occurring near the sun. Skylight polarization is most effective in clear conditions and will not give useful information in cloudy conditions (reviewed in Southwood and Avens 2010). To use this visual cue, an animal would have to have eyes able to detect polarization (Mathger et al. 2011) and have the ability to compensate for the movement of polarization across the sky (reviewed in Southwood and Avens 2010).

The light given off of the seaward horizon at night is a photic cue used by sea turtle hatchlings when finding the ocean. Loggerhead (*Caretta caretta*) and green turtle (*Chelonia mydas*) hatchlings have been found to always orient toward the brightest light presented to them. They also have been found to orient away from dark, elevated silhouettes and not necessarily toward the brightest horizon presented to them (Salmon et al. 1992).

Visual landmarks in an animal's environment can provide directional cues to a goal. This suggests use of cognitive map, where an animal can identify different sites in its habitat (reviewed in Southwood and Avens 2010). The animal can create a cognitive map by searching its environment, by taking excursions in several directions, noting landmarks and distances traveled. The animal can then reference various sites as a compass

cue for navigation (Åkesson et al. 2003). In mammals and birds, the hippocampus is responsible for spatial cognition. However, reptiles do not have a hippocampus, and it is believed that the reptilian medial cortex is responsible for spatial cognition (Wilkinson et al. 2009).

## Other Cues

Inertial cues may play an important role in sea turtle hatchlings migrating offshore and for juveniles and adults to sense oceanic movements. In hatchlings, it is believed that vestibular organs sense vibrations from the orbital motion of the water, initiating reflexes in the sea turtle that serve to maintain its heading. Within the inner ear, there are three otolith structures: the utricle, saccule, and lagena, which are extremely sensitive tilting motion. Horizontal, posterior, and anterior canals within the inner ear are sensitive to angular acceleration (Avens et al. 2003). In adult sea turtles, the same vestibular structures are believed to be used in the detection of oceanic currents, without having to surface, to derive navigational information. Inertial cues can be useful when visual cues are unavailable (Lohmann et al. 1995).

The slope of an environment can give information as to the direction of a water body and is used by several organisms such as sea turtles (Salmon et al. 1992) and aquatic or semiaquatic turtles (DeRosa and Taylor 1982).

Olfactory cues can be used in navigation by enabling the organism to be able to recognize specific sites. Sea turtles, for example, may imprint on the chemosensory cues of their natal beaches, helping them to home during the adult stage (reviewed in Southwood and Avens 2010). Odors can be carried on winds or in oceanic currents (Åkesson et al. 2003), or can come from conspecifics, helping different turtle species to navigate (Tuttle and Carroll 2005; Lohmann et al. 2008).

## Orientation and Compass Setting in Sea Turtle Hatchlings

Sea turtle hatchlings usually emerge from their nests at night and, upon emerging, immediately

orient themselves and crawl toward the sea. There are three mechanisms by which sea turtle hatchlings find the ocean, used in sequence from their initial emergence from the nest to when they locate the open ocean (Lohmann and Lohmann 1996). First, they are known to initially orient toward a lower and illuminated horizon, rather than elevated, darker shapes made by vegetation and sand dunes (Salmon et al. 1992). Second, when hatchlings reach the wave refraction zone, they use inertial cues to maintain their headings directly into waves and toward the open ocean. Third, upon swimming past the wave refraction zone, they maintain their straightforward heading using an internal geomagnetic compass (Lohmann and Lohmann 1996).

A hatchling's initial orientation toward the ocean is not driven by an inherent directional preference, which was demonstrated by Carr and Ogren (1960). When green turtle (*Chelonia mydas*) hatchlings were brought from the east coast of Costa Rica to the west coast, they oriented correctly toward the ocean. Other hatchlings were also released onto beaches with adhesive blindfolds covering their eyes. The hatchlings aimlessly moved and could not find the beach. Those who removed their blindfolds were reported to immediately orient toward the ocean.

When initially orienting toward the ocean, loggerhead and green turtle hatchlings use visual cues of illuminated, downward sloping horizons and dark, elevated silhouette cues. On clear nights, the seaward direction is more brightly illuminated than the landward direction. The landward direction also typically contains elevated dunes and vegetation, creating dark silhouettes. If no photic cues are available, hatchlings orient using elevation cues, crawling along the downward slope. The primary cue in ocean finding for loggerhead and green turtles is first perceiving darkness in the landward direction and secondarily using photic cues and downward sloping beaches to navigate to the water (Salmon et al. 1992).

The initial orientation cues used by sea turtle hatchlings can vary among species. For example, green turtles sometimes hatch on beaches with a relatively uniform slope, so photic cues may take precedence over elevation cues. Hawksbill turtles

(*Eretmochelys imbricata*) generally nest under thick vegetation, where photic cues may not be readily available to hatchlings. These hatchlings may orient toward the ocean using the slope of the beach (Salmon et al. 1992).

After initial orientation, sea turtle hatchlings crawl toward the ocean and swim directly into the waves. By maintaining a straight course through the wave refraction zone, the turtles will be lead into the open ocean. Arena experiments have shown that loggerhead and green turtles are able to detect circular motion created by waves and are able to orient their bodies accordingly. Sea turtle hatchlings will swim into waves, regardless of other cues that may be available, such as various photic cues or whether wave direction tends to be more shoreward or seaward (Lohmann et al. 1995; Lohmann and Lohmann 1996).

Beyond the wave refraction zone, wave direction does not provide cues to the landward direction, yet hatchlings will maintain their straightforward heading into the open ocean. At this point, it is believed that the hatchlings orient themselves using the magnetic field of the earth. It is unclear whether hatchlings are born with a geomagnetic compass or if it is acquired. Research suggests that the geomagnetic compass of hatchling sea turtles is acquired through experience, via exposure to light, through the hatchling's initial experience in maintaining direction during the first beach crawl, or by swimming into oncoming waves (Lohmann and Lohmann 1996).

Geomagnetic compass learning by exposure to photic cues was demonstrated in leatherback (*Dermochelys coriacea*) and loggerhead hatchlings. After being exposed to a light for 1 h, hatchlings established a course swimming toward the light. When tethered in an arena in complete darkness, the turtles oriented in the magnetic direction the light was. When the magnetic field was shifted, the turtles oriented in accordance with the shift. Hatchlings tethered in the arena without prior light exposure oriented randomly (Lohmann 1991; Lohmann and Lohmann 1993). Similar findings have been demonstrated in arena experiments when turtles selected a directional preference by crawling toward a light and by swimming

into waves. These findings suggest that directional preference is not inherent. When hatchlings are allowed to orient in response to an environmental cue, they set a directional preference that is maintained by earth's magnetic field (Lohmann and Lohmann 1996).

## Geomagnetic Navigation in Juvenile Sea Turtles

Upon swimming into the open ocean, loggerhead hatchlings, for example, swim to the Gulf Stream and end up within the North Atlantic gyre. The turtles will spend several years within the gyre until reaching reproductive maturity. Within the gyre, detection of earth's magnetic field may be imperative of the survival of young turtles (Lohmann and Lohmann 1996). Some research suggests that hawksbill hatchlings do not enter the open ocean, but stay in neritic coastal feeding grounds, avoiding currents that can lead them into the open ocean (Gaos et al. 2017).

Latitudinal direction corresponds with the earth's angle of inclination, a feature that sea turtles have been demonstrated to detect. Staying within certain latitudinal boundaries can prevent hatchlings from being swept into unfavorable habitat by oceanic currents. Within the North Atlantic gyre, loggerhead hatchlings risk entering eastward currents that divide, with one current traveling northward to cold waters. Currents in the southern portion of the gyre can carry turtles beyond their range by entering the South Atlantic current system. It was demonstrated that hatchlings can detect their position using angle of inclination and field intensity by presenting them with magnetic field features corresponding to those found in the North Atlantic gyre. It was found that when the loggerhead hatchlings were exposed to a field matching that of their natal beaches, they swam eastward, as if swimming toward the gyre. When exposed to a field matching that of the northern- or southernmost boundary of the gyre, hatchlings swam southwest and northeast, respectively. Although hatchlings and juveniles may not yet have the ability to orient toward a specific goal when within a gyre, they have an innate sense not

to stray outside of latitudinal boundaries (Lohmann and Lohmann 1994, 1996).

During the open-ocean life stage, which can last up to 10 years (reviewed in Southwood and Avens 2010), juveniles are learning the magnetic map of the ocean and associating it with various locations they can navigate to. Eventually, turtles such as loggerheads will reside in neritic feeding grounds and will seasonally migrate between habitats. It is believed that their ability to home to a target location occurs when they enter the neritic feeding stage. Juveniles will reliably return to feeding grounds they favor during seasonal migrations and also after being experimentally displaced (Lohmann et al. 2008). In contrast, leatherback and olive ridley (*Lepidochelys olivacea*) sea turtles do not feed near coastal areas but swim through the open ocean to feed (reviewed in Southwood and Avens 2010).

### Homing in Juvenile and Adult Sea Turtles

Navigational mechanisms in older sea turtles may differ from hatchling mechanisms as the turtle gains experience. While a geomagnetic map is important in navigation (Lohmann et al. 2008), juveniles and adults have been shown to employ other mechanisms to accurately home to a location when the magnetic field is disrupted.

The use of visual cues has been demonstrated in juvenile loggerheads, approximately 7 years of age, which were captured from neritic feeding grounds. In arena experiments which disrupted the magnetic field, turtles accurately oriented in the direction of their capture site by using either the sun's position or by light polarization. When no visual cues were available, and the magnetic field was undisturbed, turtles still accurately oriented toward their capture site, indicating geomagnetic navigation (Avens and Lohmann 2003). Green turtle juveniles have also been demonstrated to orient using a sun compass through exposure to an altered photoperiod, even when magnetic cues were available. While it is evident that sea turtles do employ solar and/or polarized light cues for navigation, it needs to be explored

what causes the shift in cue usage in nature (Mott and Salmon 2011).

Some species of sea turtles can take 30–50 years to reach reproductive maturity (reviewed in Southwood and Avens 2010). Once maturity is reached, turtles migrate hundreds or thousands of kilometers every 2–4 years to specific breeding sites (Lohmann et al. 2008). Several species will return to their natal beaches to nest, and it has been proposed that turtles are able to imprint chemosensory information of their natal beaches (reviewed in Southwood and Avens 2010).

Green turtles feed in the coastal waters of Brazil migrate more than 2000 km to Ascension Island in the middle of the Atlantic Ocean, which is only 11 km wide. A geomagnetic map alone may not be enough for sea turtles to accurately home to target locations. Rather, when near a target location, they may switch to or incorporate other available cues (Lohmann et al. 2008). Green turtles that were experimentally displaced homed to Ascension Island when the earth's magnetic field was seemingly disrupted by satellite tracking devices attached to their heads or carapaces. Those that were able to home to the island first used a searching strategy, traveling in indirect routes until coming into contact with another navigational cue. Chemosensory cues carried by prevailing winds traveling northwest provided a beaconing mechanism that directed turtles toward the island (Akesson et al. 2003). The displaced green turtles may have also felt surface wave patterns, as they are highly sensitive to movement (Lohmann et al. 2008). As the winds travel to the northwest, the downwind side of the island will exhibit refracted wave patterns, providing inertial signals as to where the island is located (Akesson et al. 2003).

### Orientation in Aquatic and Semiaquatic Freshwater Turtle Hatchlings

Much like sea turtles, freshwater turtles primarily use visual cues when dispersing from their nests (Congdon et al. 2011, 2015). Freshwater turtles typically emerge during the day, when visual cues

are easily recognizable (Congdon et al. 2015). However, the distance of the nest site can create issues in hatchling orientation if the nearest water body is not readily seen (Congdon et al. 2011). Therefore, other cues may play a role in wetland finding by aquatic or semiaquatic turtles, including slope, geomagnetic, or chemosensory cues (Iverson et al. 2009).

Hatchlings of snapping turtles (*Chelydra serpentina*) and western painted turtles (*Chrysemys picta belli*) orient themselves using photic cues, crawling toward the brightest illuminated horizon. They will crawl toward the brightest horizon whether or not it contains a water body reflecting polarized light (Congdon et al. 2011). In contrast, yellow mud turtle (*Kinosternon flavescens*) hatchlings orient using polarized light cues, as they were found to orient themselves in the direction of an open horizon containing a body of water that was not readily visible from their experimental arena (Iverson et al. 2009).

Many species use other visual cues to navigate. Blanding's turtle (*Emydoidea blandingii*) hatchlings orient themselves toward dark horizons, often toward riparian zones (Pappas et al. 2009). Diamondback terrapin (*Malaclemys terrapin*) hatchlings, which inhabit brackish waters, crawl toward the nearest vegetation and remain there until nightfall (Berger 1976).

Chemosensory cues can also be important in navigating toward a goal for freshwater hatchling turtles. For example, semiaquatic wood turtle (*Glyptemys insculpta*) hatchlings were observed to walk along the same paths as conspecifics during their initial migration to a brook, suggesting the use of chemosensory cues in navigation (Tuttle and Carroll 2005).

The primary orientation cue in aquatic and terrestrial turtles is a sun compass rather than a geomagnetic compass. This was demonstrated in snapping turtle and Blanding's turtle hatchlings. The hatchlings were first allowed to orient themselves using visual cues, whether in natural habitat or in an arena. When relocated to a corn field with no visual targets, turtles maintained their preferential heading and were unaffected by magnets attached to their carapaces (Congdon et al.

2015). Similar to sea turtles, this is suggestive of a directional preference that is learned through experience of movement toward a visible target. Upon completion of a successful migration, usually to a water body, the directional preference then sets the turtle's sun compass (Pappas et al. 2009; Congdon et al. 2011, 2015; Iverson et al. 2009).

### Navigation in Juvenile and Adult Aquatic, Semiaquatic, and Terrestrial Turtles

Nonmarine turtles also navigate seasonally between various habitats to exploit different resources and exhibit the use of different navigational cues than hatchlings. While hatchling yellow mud turtles navigate using polarized light cues, a sun compass took precedence in juvenile orientation. Arena experiments showed that the juveniles did not orient toward the body of water, where polarized light may be reflected, as the hatchlings did. Rather, they maintained the headings they were oriented in upon their capture (Iverson et al. 2009).

Spiny softshell turtles (*Trionyx spinifer*), painted turtles (*Chrysemys picta*), and common box turtles (*Terrapene carolina*) orient using a sun compass and are not able to orient on overcast days. These turtles were also found to adjust their orientation in a clockwise direction in accordance with an experimentally altered photoperiod (DeRosa and Taylor 1982).

Although common box turtles become disoriented on overcast days, they also become disoriented when magnets are attached to their carapaces (reviewed in Southwood and Avens 2010). While some freshwater turtles do not primarily orient using a geomagnetic compass (as with the Blanding's and snapping turtles), it cannot be ruled out as a navigational mechanism (Congdon et al. 2015). Geomagnetic compasses may not be important to all species of nonmarine turtles, as their migration distances are not as vast as marine turtles (Iverson et al. 2009).

Slope cues, chemosensory cues, and learned cognitive maps can also be used by turtles to

navigate. Orientation down slope was exhibited by spiny softshell, painted, and common box turtles, presumably as an adaptation to water finding (DeRosa and Taylor 1982). Olfactory cues may also be important to goal navigation, as eastern long-necked turtles (*Chelodina longicollis*) were found to prefer the scents from a pond to other scents (reviewed in Southwood and Avens 2010), which may aid in homing. A red-footed tortoise (*Geochelone carbonaria*) utilized visual cues to navigate in an eight-arm radial maze. The visual cues correspond to a cognitive map that is learned and utilized by the tortoise. When visual cues were obstructed, the tortoise changed its navigational strategy. It responded by searching the maze by turning down each arm in either a clockwise or counterclockwise direction (Wilkinson et al. 2009).

## Theories of Play

René T. Proyer and Tiziana Scherrer  
Department of Psychology, Martin Luther  
University Halle-Wittenberg, Halle, Germany

### Definition and Introduction

While most people will have an intuitive understanding of what *play* is, and while implicit theories on *play* seem to converge relatively well in everyday life (e.g., when talking about play experiences), there is still no consensus about its definition. The study of play is of interest to researchers across many disciplines and also across species, including (of course) humans – humans of all age groups to be more precise. In humans, mainly younger ages have been the focus of attention, although interest in the study of the role of play across the full life span has increased over the past few years. However, a universally accepted definition of play in humans and animals is still missing. In particular, in the study of play behavior in animals, it can be difficult to differentiate play from other behaviors based on observations alone (e.g., stereotypical behavior in animals held in captivity). Hence, criteria have been developed that can be applied to the study of play. Burghardt (2005) suggested five criteria that identify play across species, play is:

- (1) Incompletely functional in the context in which it appears; (2) spontaneous, pleasurable, rewarding, or voluntary; (3) differs from other more serious

behaviors in form (e.g., exaggerated) or timing (e.g., occurring early in life before the more serious version is needed); (4) is repeated, but not in abnormal and unvarying stereotypic form (e.g., rocking or pacing); and (5) is initiated in the absence of severe stress. (cited after Graham and Burghardt 2010, p. 394)

This list of criteria helps us to differentiate play-behavior from related behaviors, such as those driven by curiosity or stereotypical behavior. It is argued that play can have both immediate and long-term benefits. Finally, Burghardt (2005) defined play in animals as a “[...] repeated, incompletely functional behavior differing from more serious versions structurally, contextually, or ontogenetically, and initiated voluntarily when the animal is in a relaxed and low-stress setting” (p. 82).

### Why Studying Play Matters

The question of why animals (including humans) play has stimulated research in many different areas (see, e.g., Fagen 1981; Huizinga 1938/1955; Millar 1968; Pellis and Pellis 2009; Sutton-Smith 1997). Murray (1938) has argued that there is even a *need for play* in humans. In his taxonomy, a need is understood as “a construct [...], which stands for a force [...] in the brain region, a force which organizes perception, apperception, intellection, conation and action in such a way as to transform in a certain direction an existing, unsatisfying situation” (p. 123). He lists play as one of these needs: “play (playful attitude). To relax, amuse oneself, seek diversion and entertainment. To ‘have fun,’ to play game. To laugh, joke and be merry. To avoid serious tension” (p. 83) and further argues that the need to play is characterized by a tendency to perform activities for joy alone and without further reasoning, or to escape reality. Developmental psychologists have acknowledged the important role play has for various stages in life. For example, Piaget (1945) described a form of tension between assimilation (having a schema that is imposed on the world) and accommodation (imitation of something that has been observed or done in the past, where the schema is modified) – play occurs if assimilation exceeds accommodation. Hence, for Piaget, learning and exploration are associated with

play and imitation. He developed a stage model of different levels of play that follow a specific developmental process: from a sensory- motoric phase at the beginning to more advanced levels in higher stages of development.

The developmental psychologist Erik Erikson argued that adults with higher vitality and potentially higher playfulness have greater resources from childhood that make it easier for them to access a second reality aside from their adult life. They are able as adults to access their childhood world that is associated with play and imagination. He suggests that adults play for recreation and that they use this experience of an alternate reality in play to relax. Work is a competitive environment and play poses a possibility to escape these environments. However, in Erikson's reasoning this is tied to work inasmuch as adults have learned that "Only he who works shall play" (Erikson 1959, p. 89). Erikson argues for a *play* stage in human development, which would be after the early-childhood stage (his second stage, which is aimed at autonomy with "will" as its basic strength) and would precede the school-age stage (which is aimed at industriousness and with competence as its basic strength). The play age can foster initiative because its "psychosocial crisis" is the conflict between initiative and guilt, and the basic strength associated with this age is purpose (core pathology: inhibition). At this stage, play in children transforms from playing only for oneself to playing with a world shared with others (Erikson 1959). This is accompanied with a sense of mastery – not only with respect to toys and things, but also mastery of (new) experiences. For adults, many definitions of the need for play focus on its contribution to relaxation, enjoyment, and or fun (e.g., Murray 1938; van Fleet and Feeney 2015). However, this might limit our understanding of what play and playfulness could have as forms and functions outside of this realm (e.g., for problem-solving or intellectual achievement), this point will be described in more detail later on.

Bateson (2006) sees play as a driver for evolution (or a driving force in evolution), specifically as an "adaptability driver." In this sense, play facilitates adaptation to environmental changes

and the application of novel approaches (e.g., those that affect survival). This is associated with enabling the creativity and innovation that are needed in these situations. Bateson and Martin (2013) list six defining features of play, as follows: (1) intrinsic motivation, fun; (2) the behavior is nonserious (Bateson and Martin see play as the antithesis of work or serious behavior); (3) actions or thoughts in humans are related to novelty and play is a generator of novelty; (4) actions or thoughts are repeated and may be incomplete or exaggerated in comparison with nonplayful behavior; (5) specific conditions need to be met and play does not occur when the individual is ill or stressed; and (6) "playful play (as distinct from the broader biological category of play) is accompanied by a particular positive mood state in which the individual is more inclined to behave (and, in the case of humans, think) in a spontaneous and flexible way" (p. 13). Bateson (2010) suggests that two processes could explain how adaptive process might work, namely: either one individual discovers a solution through play, which then spreads via social learning, or many individuals identify a solution through play posed by the environment. Work on play as an adaptability driver would then indicate that "those individuals that were able to express the beneficial trait spontaneously at lower cost were able to compete more successfully. In this way, playful activities could affect the evolution of the individual's descendants" (Bateson 2010, p. 9).

Bishop and Chace (1971) also use the term "playful play" when describing the potential contributions of play and playfulness to creativity. They argue that the motives and processes that are involved in play are highly similar to those of the creative process. Therefore, play would facilitate the learning experience of these respective cognitive and behavioral process, which then would facilitate creativity.

## Play Theories

Play has frequently been described as a process dedicated to the acquisition of skills and as a way of training or preparation for specific tasks and

behaviors in adulthood (cf. Barnett 1990). This perspective has been interpreted as a functionalist view of play and it has entered the literature under the broader term of *Exercise Theories*. It has also been proposed that play could be used to assess the development of ones' offspring or to assist in further development. In addition, play facilitates bonding between parent and child. Rubin et al. (1983) suggested six criteria for play, namely:

- (1) Play is not governed by appetitive drives, compliance with social demands, or by inducements external to the behavior itself; instead play is intrinsically motivated;
- (2) play is spontaneous, free from external sanctions, and its goals are self-imposed;
- (3) play asks "What can I do with this object or person?" (this differentiates play from exploration which asks "What is this object /person and what I do with it/him/her?");
- (4) play is not a serious rendition of an activity or a behavior it resembles; instead it consists of activities that can be labeled as pretense (i.e., play must comprise non-literality);
- (5) play is free from externally imposed rules (this distinguishes play from games-with-rules); and
- (6) play involves active engagement (this distinguishes play from daydreaming, lounging, and aimless loafing). (Coplan et al. 2006, p. 75)

Burghardt (2005) gives an overview on the most eminent theories in the field and points out that one major characteristic of play is that it refers to make-believe type of activities, or *as if* behaviors or pretending to do something. Most often in research on play in children, these *as if* behaviors have been associated with behavioral flexibility and adaptive types of behaviors. Others have also emphasized seeing play as an exploratory and information-seeking activity that elicits arousal (e.g., Berlyne 1960). In this framework, play is aimed not only at increasing the information in well-known environments but also at increasing novelty and complexity – potentially to prevent boredom from occurring. A further frequently mentioned characteristic of play is that it does not serve any immediate purpose. No purpose other than seeing the process of playing as being *fun*. While others have stressed the importance of play for the development of the self and self-realization in particular (Henricks 2014). But why do animals play? The following paragraphs will provide a brief overview of some selected theories of play.

The *Surplus Energy Theory* (SET) posits that play occurs in times when there is a surplus of energy (e.g., due to good nutrition conditions) and when there are no external demands that need to be satisfied, and that play eventually costs energy. In these cases, extra energy can be spent with play. One might argue that the SET suggests that the degree of exerted playfulness is a function of available energy. It has been observed that those animals that need comparatively less energy for movement (e.g., birds) play more than those who have greater costs in terms of energy for movement (Burghardt 2005).

Burghardt (2005) developed the *Surplus Resource Theory* (SRT) to describe how play occurs and what resources or environmental factors (e.g., available food) may play a role. Burghardt describes necessary but not sufficient factors that can enable play, with a special focus on an extended juvenile period (that demands specific parental behavior; e.g., protection), that is:

- (1) There is sufficient metabolic energy [...].
- (2) The animals are buffered from serious stress and food shortages [...].
- (3) There is a need for stimulation to elicit species-typical behavioral systems or to reach to an optimal level of arousal for physiological functioning (e.g., there is susceptibility to boredom).
- (4) There is a life-style that involves complex sequences of behavior in varying conditions, including diverse and unpredictable environment and/or social resources. (Burghardt 2005, p. 172)

Thus, Burghardt's approach specifies the conditions and circumstances that facilitate or hinder the occurrence of play. He proposes a gradation in the processes (primary, secondary, and tertiary) of play. Those at a higher level would also enable an individual to transform physical to mental play or to provide resources for novel behavior and creativity (Burghardt 2005).

*Recuperation Theory* posits that play, because of the muscular reactions, could extinguish toxic substances and therefore, like sleep, leads to the recuperation of the exhausted systems (Burghardt 2005). Similarly, *Recreation Theory* suggests that because of the Industrial Revolution, most workers have less control about when, how long, and what they work and that play serves a recreational

purpose but could also be seen and as a possibility of self-determination (Burghardt 2005).

*Semblance Theory* argues that the significant part of play is “its quality of [...] ‘as-if’, pretend or pretense” (Burghardt 2005, p. 39) – or role-play from a more current perspective. The core of *Exercise Theories* (e.g., Fagen 1981) and variants thereof is that play does not have any immediate functions per se (except perhaps from physical practice) and does not necessarily lead to a product in its narrow sense. Its sole function is to prepare an animal for its future survival. Play behavior and playfulness is an expression of and is driven by *instinct*. Aside from physical education, the aim of play is to master specific skills, namely, those that are important for later survival. Along these lines, *Autotelic Theory* suggests that the aim of play is its behavior itself, and there is no higher goal. Meanwhile, *Socialization Theory* suggests that social play is important to understanding social structures and to establish one’s role in a group. Finally, *Cognitive Theories* of play describe play as important in cognitive development.

Panksepp (1998) proposes a neuro-evolutionary model in which he also considers play as being one of the components of evolution. He argues that *primal* emotions or “core emotional affects may reflect the neurodynamic attractor landscapes of a variety of extended trans-diencephalic ‘energetic’ action systems – e.g., SEEKING, FEAR, RAGE, LUST, CARE, PANIC, and PLAY – which need to be defined in neural terms” (Panksepp 2005, pp. 32–33; capitalizations by original author). He postulates that *joyful PLAY* is an emotional system that is shared by all mammals and that: “Young animals play with each other in order to navigate social possibilities in joyous ways. The urge to play was also not left to chance by evolution, but is built into the instinctual action apparatus of the mammalian brain” (Panksepp 2005, p. 54). He sees joint play (rough-and-tumble play) as a basic process for a broad variety of social skills (e.g., social support and friendships). The experiences during play would help in the programming of specific circuits within the brain and may also have an impact on the activation of certain genes. Therefore, this process is then associated with neuronal growth and emotional homeostasis.

Overall, Panksepp’s (1998) framework proposes circuits or overlapping networks in the brains of mammals that have an impact on playfulness. From play, specific emotions emerge, namely, joy and glee, and happy playfulness. Overall, the contribution of this work seems to be to highlight the relevance of the neuropsychological aspects of play and that certain regions in the brain may be activated during play behavior. Most certainly, further work in this area needs to be done.

Csikszentmihalyi and Bennett (1971, p. 45) see play “as a state of experience in which the actor’s ability to act matches the requirements for action in his environment. It differs from anxiety, in which the requirements outnumber the ability, and from boredom, in which the requirements are too few for the ability level of the actor.” They argue further that “Play is action generating action: a unified experience flowing from one moment to the next in contra-distinction to our otherwise disjoint ‘every-day’ experiences” (p. 45). Another characteristic of play is that possibilities for an uninterrupted flow of actions is given, which is combined with a lack of self-awareness as people playing enter a self-constructed reality. They see play as being of an episodic nature – emerging when everyday life becomes too worrisome and ending when the play experience is perceived as boring. Csikszentmihalyi and Bennett (1971) also propose that there can be quick shifts between states of worry, play, and boredom (*monistic interludes*). Play is particularly suitable for enabling intrinsic rewards because it exists relatively independently from external rewards and flow-experiences would be common in various forms of play. Csikszentmihalyi argues that the components of playfulness include an awareness of alternative goals and the ability to choose (freely) among these goals, and adds that highly creative people can combine both playfulness and discipline.

## Playfulness

*Playfulness* is frequently understood as an individual difference variable at the trait-level (i.e., relatively stable across time and situations). In

short, one might define playfulness as the propensity to play and that individuals differ in how much they want to play (e.g., in terms of time, intensity, or variability). Hence, play is a behavior that is associated with the personality trait of playfulness. The latter is typically conceptualized multidimensionally and, thus, relates to different expressions of behavior. A more differentiated definition of playfulness is:

An individual differences variable that allows people to frame or reframe everyday situations in a way such that they experience them as entertaining, and/or intellectually stimulating, and/or personally interesting. Those on the high end of this dimension seek and establish situations in which they can interact playfully with others (e.g., playful teasing, shared play activities) and they are capable of using their playfulness even under difficult situations to resolve tension (e.g., in social interactions, or in work-type settings). (Proyer 2017, p. 114)

This definition is accompanied by a structural model of playfulness that differentiates among Other-directed, Lighthearted, Intellectual, and Whimsical (OLIW model) variants of playfulness.

In humans, playfulness and play have mainly been studied in infants and children. However, as early as 1977, Lieberman suggested that playfulness permeates into adulthood and is also of relevance there:

By this [playfulness] I mean the lightheartedness that we find as a quality of play in the young child's activities and, later on, as the combinatorial play essential to imagination and creativity. I, therefore, see playfulness as behavior that goes beyond the childhood years; and, through its component parts of sense of humor, manifest joy, and spontaneity, it has major implications for childrearing practices, educational planning, career choices, and leisure pursuits. (Lieberman 1977, p. xi)

She later notes that “playfulness as a quality of play would developmentally transform itself into a personality trait of the player in adolescence and adulthood” (Lieberman 1977, p. 23). In line with expectations, there is evidence that trait measures of playfulness are positively associated with the play behavior that has been reported in diary studies (Proyer 2017). Other research supports the notion of relations with different indicators of well-being, including relationship satisfaction,

creativity, humor, and academic performance (to name but a few).

## The Special Case of Sexual Selection

One important question is how a behavior such as play may be beneficial from an evolutionary perspective. It has already been mentioned that an important argument may be that play facilitates survival (e.g., training of fighting or flighting skills, or increasing physical strength). Chick (2001) proposes that adult playfulness has a signal function when selecting partners for long-term relationships (in heterosexual couples). He suggests that observed playfulness in men signals low aggression to their partners and high vitality (fecundity) to men when observed in their potential partners. Subsequent research has shown that playfulness is a desired personality trait of younger adults when thinking about a potential partner (in the United States). This notion has received support in later studies, which show that playfulness ranks comparatively high if young students rank order a list of different characteristics (this study has been replicated with data from Switzerland). There is evidence for assortative mating and/or social homogamy when seeking partners for long-term relationships (Chick et al. 2020). Play behaviors should also have high observability and it seems, therefore, to be a good source of information for those selecting partners for long-term relationships. Data from studies on playfulness have shown robust self-other-agreement, and there is evidence for implicit cues about greater playfulness among unacquainted people in their written self-descriptions (e.g., the usage of positive emotion words).

## Conclusion

Play is an important part of the life in many species. It seems particularly common in mammals and animals with relatively low energy costs for movement (e.g., birds), but might be rare in other species. However, Burghardt (e.g., 2005) argues for play behaviors in other species (e.g.,

fish, amphibians, or reptiles). Play might serve both immediate and long-term effects. The degree to which such effects are present is an ongoing discussion in the field and can be difficult to evaluate (e.g., when being interested in its distinct effect across the life span). A recurring topic of interest is the question of the function of play, such as for the development of children (see, e.g., Pellegrini and Smith 1998). As noted earlier, there is a frequent reference to play as being “fun” as a proximate reason for play, but are other functions observable? For example, it has been argued that play may be associated with brain growth (or growth with play behaviors) and development and, thus, is important to evolutionary processes (see, e.g., Byers and Walker 1995). Pellis et al. (2019) summarized several studies and conclude (1) that limiting play in rats and hamsters during their juvenile period results in adults that have physiological and anatomical changes in their medial prefrontal cortex, as well as reduced social and cognitive skills and (2) that animals raised with playful peers have better social and cognitive skills than those raised solely with adults. While this seems replicable with domesticated rats, results differ with wild rats. Pellis et al. (2019) suggest that it may be that domesticated adults are less likely to play with juveniles and therefore the juveniles do not experience the kinds of activities critical for brain development. They concluded that adult wild rats may provide more opportunities for play and are more cooperative in their play with juveniles. Hence, there seems to be support for the notion that play among juvenile animals appears to have an evolutionary purpose that involves brain development.

Taken current developments into account (e.g., in the realm of gamification or playful learning-initiatives), it is surprising to see how comparatively little research is done across disciplines. For example, psychology seemed to have only little interest in the study of play and playfulness in adults. One might expect that, for example, an individual difference approach in the study of the potentially beneficial effects of gamification (e.g., using trait playfulness as a moderator) would contribute toward a better understanding

of working mechanisms and might help to make recommendations for practice. While progress has been made in the study of play (cf. Graham and Burghardt 2010), many open questions still exist.

## Synonyms

ToM

## Definition

Theory of Mind is the ability to represent one's own as distinct from another's mental states including beliefs, desires, and intentions to potentially change the mental states or behaviors of others.

Theory of Mind (ToM) is one of the most important cognitive mechanisms underpinning social interactions in humans. It is the capacity to represent mental states of oneself and of others in order to understand, predict, and manipulate their behavior or mental states. In the day to day life, we attribute to our fellow humans a mind that has beliefs, desires, knowledge, and other mental states. Based on these attributions we can successfully interact in the complex human social system. Teaching and cooperating as well as deceiving and competing are human abilities that all take into account the mental states of the interacting partner. Thus, having ToM is a central part of human cognition but is this ability unique to our species or might we share it with at least some nonhuman animals?

In their seminal publication “Does the chimpanzee have a theory of mind?” Premack and Woodruff (1978) were the first researchers to approach this question from a comparative psychologist's perspective. Their enculturated chimpanzee, Sarah, was presented with videos

depicting a person who wanted to obtain a goal, such as reaching for an inaccessible food, trying to free himself from a locked cage, or trying to play music from an unplugged phonograph. All the presented situations had in common that the actor was missing a crucial item in order to solve the problem at stake. Sarah was then presented with two pictures. She was asked to indicate towards either a picture with an item that helped to solve the task or a distractor item that would not. The tested individual pointed towards the correct items from the very start of the experiment. The authors interpreted this result in such a way that the chimpanzee understood the intention of the experimenter and pointed towards the solution of the problem. However, the study was later criticized and re-interpreted. Sarah did not necessarily choose correctly based on the understanding of the goal of the experimenter; instead she might have been pointing towards the picture with the correct item because it had been seen more often in association with the other items in the videos (Povinelli et al. 1998). Ever since this experiment, researchers in comparative cognition have searched for evidence of ToM in the animal kingdom.

In comparison to testing ToM in humans, non-linguistic animals cannot be verbally asked about their beliefs. One of the most prominent experiments in testing the human development of ToM is the false belief task that, in its original form, required the test subject to understand human language. In a typical false belief task (e.g., Wimmer and Perner 1983), a child is presented with a story. In one story, the character Maxi hides his chocolate in a drawer (location A). After Maxi leaves the room, his mother moves the chocolate into a different drawer in the same room (location B). Subsequently, test subjects are asked where Maxi will search for the chocolate when he returns. Until the age of three, most children are unable to ignore their own knowledge of the true location of the object and indicate that Maxi will look where he believes the chocolate to be, namely in drawer A. Via this test, subjects are explicitly asked about their personal beliefs about the knowledge state of Maxi. If the child can differentiate between his/her own state of

knowledge (actual location of the chocolate) and the Maxi's false belief the child is considered to have passed the test and thus have developed ToM. Most children over three can represent false beliefs successfully. This experiment is often referred to as the "Sally-Anne" task (Baron-Cohen et al. 1985) and its variants have become one of the most important ways to study ToM in human children as well as nonhuman animals.

In the evolution of ToM in humans as well as animals it is hypothesized that in an increasingly complex social system it is adaptive to predict, manipulate and learn from others (Brothers 1990). Thus, the occurrence of cognitive abilities in a given species that are necessary for elaborated social interactions are positively correlated with the species' level of social complexity. This is in line with the social intelligence hypothesis (Chance and Mead 1953; Humphrey 1976; Jolly 1966), which states that selective pressures – especially competition and cooperation – have played an important part in the evolution of intelligence. Cognitive abilities like individual recognition, knowledge about previous social interactions, and relationships help to interact with others. Especially in cooperative and competitive situations it is highly advantageous to additionally predict the future behavior of others by "reading" their mental states like understanding their knowledge, perceptions, beliefs, goals and intentions. The main problem in experimental designs is to differentiate mere behavioral reading from understanding intentions (i.e., the mental states of a conspecific), as we do not have direct access to the desires, beliefs, and goals of animals or other humans but have to infer such mental states from how they behave, what they do, and in humans – what they say.

As a response to the seminal study of Premack and Woodruff (1978), a categorical differentiation between three different levels that an organism or more generally, intentional systems, can have was proposed by Dennett (1983). Zero-order intentional systems do not have any beliefs and desires, and consequently they have no mentality, no intelligence, no communication, and no intentionality at all; first-order intentional system have beliefs

and desires but no beliefs and desires about beliefs and desires; second-order intentional systems have beliefs and desires *about* beliefs and desires – both those of others and itself (Dennett 1983). An example for a zero-order intentional system is a simple feedback system like a thermostat. The goal of the thermostat is to keep the room temperature at a specified level and it responds to temperatures below the critical value. Based on the feedback of the thermostat, heating will be prompted and stopped as soon the set temperature is reached. While the thermostat has the goal to keep the temperature at the specified level, it does not have any beliefs, desires, or intentions. A typical example in the animal kingdom is that of bacteria with photo-taxis. The bacteria move in the direction of light but will stop moving when sufficient light is detected. First-order intentional systems have their own beliefs, desires and intentions in contrast to the zero-intentional system, which only instantiates its goal via a simple feedback mechanism. A cat might believe that a mouse is hidden in the burrow, and it lurks in front of it in wait. It is hard to discern whether the behavior is based on a complex combination of feedback mechanisms or whether the behavior is based on a belief or desire, even though at first sight it might seem clear that there is a difference between the two. Does the cat lurk in front of it because the smell in addition to the burrow is sufficient to trigger the behavior, or rather because it has a belief that there is a mouse hiding? Similarly, identifying whether or not a particular species has a first-order from or second-order intentional stance is also often hard. In a second-order intentional animal it is necessary that it can represent the belief of another individual. When a Eurasian jay hides and stores an acorn for winter it tries to do so without being seen. But when it is seen, it will try to re-cache the same acorn at a different place in order to prevent the competitor from pilfering its stores. In cases where it cannot avoid being observed the jay will re-cache the acorn multiple times in order to deceive the observer from the actual hiding point. If the jay has first-order intentionality it will only respond to the absence or presence of the competitor or a specific body part like the eye. Alternatively,

when the bird bases its deceptions on its own beliefs about the beliefs of the observing individual, it will (like Maxi in the false belief task) be able to differentiate its own knowledge from the belief of the competitor. Thus, only when the jay bases its decisions on its own representation of the other's mental states, such as false beliefs, can it then be considered to have second-order intentionality and thus ToM.

Differentiating whether the observed behavior is based on the more complex social cognitive ability ToM or on a lower level mechanism is one of the main aims of researchers in this field. Another typical example of applied animal behavior is the following: A nesting piping plover will defend its nest by trying to lure a predator like a fox away from it (Ristau 1991). In order to do so, the bird will imitate an injury by dragging one wing behind as soon as a fox approaches too closely to the nest. When the fox starts to follow, the bird will continue with the behavior until the predator is far enough away from the eggs. Then she will fly back to nest and the fox has successfully been led astray by her deceptive behavior. By deceiving the fox with the broken-wing display one could at first blush argue that the plover intentionally deceived the predator in order to protect its nest. According to Tinbergen (Tinbergen 1963), one still needs to differentiate proximate causes including the underlying mechanism (How is it performed?) and the ontogenetic development (How did it develop?) as well as the ultimate causes including the functional level (What is it for?) and the evolutionary history of the behavior (How did it evolve?). While the answer to the adaptive value question of the behavior is clearly that the plover deceives the fox in order to protect its eggs, clarifying the underlying mechanism, whether this is a lower level cognitive mechanism or complex social cognitive skill, needs further investigation. This directly relates to the questions of ontogeny and phylogeny – is the deceptive behavior shaped by evolutionary adaptations or rather based on the learning experiences during the ontogenetic development of the individual? While it seems clearer that the nest-protection in the example is an evolutionary adaptation with little variation

across individuals within the species, other behaviors are less easy to qualify. In principle, many investigations around ToM are attempts to clarify precisely the question what the underlying mechanism of the observed behavior is.

But what are the specific benefits of having a ToM? It is hypothesized that it qualitatively increases the positive outcome of interactions with others, for example by understanding the role of the cooperative partner, understanding perspective during imitation, as well as understanding intentional communication and deception. In highly complex social systems it seems necessary to have a more domain general ability to predict the behavior of others than mere behavioral reading as understanding the mental states leads to more efficient and flexible behaviors, especially in new situations. Still, the interpretations of supposedly positive evidence for ToM in animals are still debated, despite the large number of studies. This has led to discussions around whether the existence of ToM in humans and the potential lack of evidence of ToM in animals is not about a gradual increase of abilities but an absolute difference (Povinelli et al. 2000). In the Reinterpretation Hypothesis (Povinelli et al. 2000), the authors state that in animals it suffices to explain the complex behaviors via low-level perceptual rules like gaze-following during pointing behavior. Additionally, they point out that first-order intentional states are generating complex social behaviors but that sometimes the second-order intentional states prompt the first-order intentional states that produce those behaviors, but only in humans. Thus, humans do sometimes base their behavior on mentalizing the mental states of others but not always do so.

Early studies investigating ToM concentrated on the ontogenetic development in humans and the evolutionary development by testing non-human primates. Only later did the field broaden and investigations among monkey and avian species started. The investigations in corvid species have turned out to be particularly fruitful. Based on the convergent evolution of social intelligence (Emery and Clayton 2004) and the identification of avian brain areas that are equivalent to the mammalian prefrontal cortex (Jarvis et al.

2005), that show learning-induced changes (Lee et al. 1998), it has been suggested that corvids can indeed attribute mental states to others (Keefner 2016). By expanding the investigation of ToM to nonprimate species, the potential influence of social complexity on the evolution of ToM gained momentum and a broader comparative perspective on the evolution of ToM was added.

Thirty years after the first experiment on ToM in a chimpanzee, Call and Tomasello differentiated two main strands of research in chimpanzees that try to provide evidence ToM (Call and Tomasello 2008). The first way to infer the existence of ToM is to conduct studies that test the understanding of (1) goals and interactions either by varying possibilities of (a) getting/finding food, (b) reacting to a partner's actions, or (c) imitation. The second way is to test animals' understanding of (2) perception and knowledge of others either via (a) gaze following, (b) communication, or (c) food competition. Similarly to this way of categorization, experiments about ToM have been differentiated according to the mental states of the interaction partner namely perceptual states, knowledge states, desire states, and belief states (Apperly 2010).

## Perceptual States

Being aware of the perceptual state of another individual means to be able to represent what the other individual is able to perceive. For instance, the Eurasian jay from our previous example should only recache its acorn when the other individual was actually able to see the initial caching event. It should leave the acorn in its initial cached location if the competitor was not able to see where the acorn had been cached. This would be an example of representing the perceptual state of seeing in order to adjust the behavior according to the information the other individual was able to see. It has been argued that apes adapt their communicative signals according to the visual attention of the communicative partner (Tomasello et al. 1994). Similarly, the piping plover from

our previous example of deception adjusts its broken-wing display based on the visual orientation of the predator (Ristau 1991). In corvids it is known for instance that food caching California scrub-jays adjust their caching behavior based on the attentional state of the potential pilferer (Dally et al. 2005). While all of the above examples may have ToM as an underlying mechanism, the behaviors could be based on simpler behavioral rules. All the animals might only take into account whether they see or do not see any of specific physical features that might be highly correlated with the attentional status of the interaction partner. This could for instance be the presence or absence of the eye, or the orientation of the head or the body. As a result of these concerns, a number controls have been designed in order to differentiate between the adjustment of the behaviors based on behavioral rules and behaviors based on the understanding of the perceptual mental state of the other ("seeing"). Povinelli and colleagues tried to differentiate exactly these alternative possibilities (Povinelli et al. 1996). They presented young chimpanzees with two holes in a transparent barrier. On the side of the experimenter a box with food on top was positioned out of reach of the tested individuals. The animals were trained to beg for food by reaching with their arms through the holes in the glass. Different conditions were then presented to the test subjects. Either the human experimenter looked in the direction of the chimpanzee or away, had his eyes or mouth covered with cloth, held a bucket to cover their head or rested it on a shoulder or similar. The tested individuals were immediately able to differentiate when the experimenter had his body turned away from the chimpanzee or was facing at the chimpanzee but were not able to differentiate the other conditions early in the experiment. However, after a while, the subjects started to learn the differences in the other conditions, and reduced begging behavior. As a result, the researchers argued that the chimpanzees do not have an understanding of the attentional/perceptual state of the experimenter, but they were able to learn and thus associate the successful situations with reward and increased begging behavior.

Following the gaze of others is an important feature in primates when looking for food, identify predators, and keeping track of social interactions within a group. Based on the features of the primate eye like forward facing and the existence of a white sclera, it seems easy to follow gaze. This feature is less conspicuous in some species, such as ravens, but still does convey important information. Corvid species follow the gaze of individuals of the same species and different species like humans when looking into the sky right after fledging. This is due to the importance of gaze-following for anti-predator behavior. It is possible to habituate and thus stop various species such as chimpanzees and common ravens from following the gaze of an individual that looks repeatedly into the sky without a predator flying above. While chimpanzees are habituated and reduce gaze-following to regular upward looking after four to five years, ravens stop gaze-following from the second month after fledging when frequently presented with an uninformative gaze. Again, it might be that the test subjects either learned to inhibit socially triggered orientating behaviors, or habituation might be based on the understanding of the visual angle of the looking individual and thus be an indicator of ToM (Povinelli et al. 1996).

In the barrier test it is supposed that individuals can gain information like the location of food by following the direction of the gaze of conspecifics or heterospecifics. During the barrier test an experimenter stands in the middle of a barrier where he has visual access to both the test subject and the part of the compartment that the subject cannot see. When the experimenter then looks towards a spot behind the barrier that the subject cannot see it should, if it understands the experimenter's visual perspective and the barrier, start searching for food behind the barrier. Alternatively, when the bird only responds to the orientation behavior of the experimenter it will look on its own side of the barrier without taking the visual angle and the barrier into account. In case the tested individual does look behind the barrier, it is generally supposed that it understands angle, barrier and perceptual state of the looker. Great-apes as well as ravens do show some kind of understanding of the

visual barrier but only later in their ontogenetic development (Bräuer et al. 2005; Bugnyar et al. 2004). This makes it hard to discern whether the behavior is based on associative learning or whether they actually do understand the visual perspective of the other.

The following experiment has implications for understanding perceptual states but also knowledge states. When concentrating on the perceptual states, the study by Hare et al. (2001) is a competitive situation where gaze following can help to gain food. As exemplified in this experiment, two chimpanzees, one subordinate and one dominant, were looking into a central cage. Both individuals were in separate compartments either side of the central cage, with two barriers partially occluding their view of the latter. An experimenter placed food behind the barriers where only the subordinate could see the reward. In some of the conditions the dominant either did not see the baiting or the food was later moved once more when the dominant was not looking. Subordinates always saw the complete baiting procedure and additionally the visual access of the dominant to the baiting. If subordinates are sensitive to the gaze of the competitor they should adjust their behavior according to what the dominant sees or does not see and thus be able to attribute the perceptual state of the competitor. However, it is also possible that individuals not only represent the perceptual state of seeing but also the dominant's knowledge state in order to infer what this protagonist has or not has seen and thus what he does or does not know about the location of the food (Hare et al. 2001). According to this interpretation, the subordinate can differentiate between two knowledge states that the dominant might have: in other words, subordinates chose the food that the competitor was unaware of (ignorant) as opposed to the food that the competitor was aware of (knowledgeable). By this account, the attribution of perceptual states can subsequently lead to the attribution of knowledge states. Critics, however, would argue that a lower-level mechanism could explain such results, for it is far from clear that the subordinate needs to make this differentiation based on an understanding of knowledge states, i.e. of mind reading.

Instead the subordinate could differentiate based purely on behavioural cues~ for a dominant individual that knows where the food is might behave quite differently to an ignorant dominant who does not know.

When we evaluate these experiments about perceptual state attribution, there is some evidence that visual co-orientation of the focal individual may be based on representing the perceptual state (what the competitor or collaborator may see). Critics claim, however, that the co-orientation is based on lower level mechanisms instead of a high cognitive attribution. Namely, it could be that animals can co-orient and look into the same direction as others to find an object of interest without necessarily attributing any perceptual state to the other individual. It is for both of these reasons that tests of knowledge attribution in nonhuman animals are contentious.

## Knowledge States

As already introduced, representing perceptual states such as whether the competitor can or cannot see is different from the ability to represent the knowledge state of another individual. Knowledge attribution additionally requires the individual to understand that the competitor *knows* where the food is as opposed to simply to *have seen* where the food is, so this must be based on tracking multiple previous observations of the protagonist rather than rely only on the individual's current perceptual state. In the competitive foraging paradigm of Hare and colleagues, the subordinate individual had to track the different opportunities of observation that the dominant individual had access to and attribute whether the dominant was able to see where the food was hidden and thus did or did not know where the food was currently hidden.

California scrub-jays have also been shown to differentiate between knowledgeable and ignorant competitors during re-caching events (Emery and Clayton 2001). In general, food-storing corvid species cache food for later consumption. This might be costly, as observing competitors might pilfer these caches. As a counter-strategy the

caching individuals may re-cache the food once the observer has left the scene. Cachers have been shown to actually re-cache only in those instances where they have been observed at the initial caching event. In order to test this, scrub-jays were allowed to cache wax worms in trays in a condition where a competitor had visual access during the caching event and in another condition when visual access was blocked (Emery and Clayton 2001). Three hours later the cacher was allowed to re-enter the compartment and either recover or re-cache the previously cached items by providing them with the previous tray plus a new caching tray. Birds re-cached more often during recovery when they have been observed during the original caching event. Additionally, some of the birds were allowed to pilfer caches from other individuals and thus had both experiences of observing and pilfering. While birds who had never pilfered beforehand re-cached very little in both observed and private conditions, the birds who had the additional experience of pilfering re-cached more often in the observed condition. This result shows that experience played a key role. Recaching when in private was not a hard-wired response to having been observed during caching, but rather it depended on whether the birds had had the experience of being a pilferer in the past. Note that the result cannot be explained in terms of simple behavior reading because re-caching always occurred in private once the observer had left the scene, and thus the cacher could not be responding directly to the competitor's behavior at the time of action (re-caching). Furthermore, re-caching was neither rewarded nor punished: just a one-off response in the absence of any training. Taken together these results suggest that the jays are capable of experience projection, of taking another's perspective. Subsequent experiments showed that the behavior also depends not only on whether or not they had been observed when caching but by whom (Dally et al. 2006). If the observer was their mate with whom they share their caches, then no re-caching occurred. By contrast if the observer was a potential pilferer then re-caching occurred and the amount of caches that were consumed as opposed to re-cached depended on the potential

threat imposed by the observer, i.e. whether they were dominant or subordinate to the cacher (Dally et al. 2006).

Common ravens have also been tested in a similar design but with three conditions. They were tested in situations when they were observed through a wire-mesh window; alternatively, the wire-mesh window was visually barred with a curtain or in a peep-hole condition (Bugnyar et al. 2016). While the observed condition with full visual view and the private condition with blocked visual access are similar to the caching experiments in scrub-jays, the peephole condition is a new variant. In this variant the window between the observer and the storer was visually blocked, except that one of two small peepholes was left open. In this situation, no real competitor was present but recordings of a conspecific were played back via a loudspeaker. By providing a peephole only, the cacher cannot see a potential observer while it caches based on the limited visual perspective of the cacher. Thereby the typical critique of behavior reading is not applicable that the cacher might have used when seeing the potential pilferer. In order to use the correct cache protection strategy, the raven therefore needs to understand the peephole as potentially providing a visual perspective to a competitor without seeing the observer itself. Therefore, the cacher has to infer that the bird might have the opportunity to observe the caching behavior as it could "hear" the presence of a bird it could not see. The playback of another individual in the adjacent compartment provides the information about the absence or presence of a competitor. Thus, when ravens were tested in the peep-hole condition, they responded to the playbacks as if a conspecific potential pilferer with visual access was present and based their cache-protection behavior on this information. The elegance of this design is that neither playback alone nor the peephole per se elicit cache protection strategies but in combination provide information about a potential competitor. When given access to only one of the two peepholes the caching individual was not able to adjust caches according to the visual angle of one of the peepholes. In other words, the cacher was not able to adjust to the actually perceivable visual

angle but acted as if the bird would have had full view of the compartment.

Attributing knowledge states to competitors even when no behavioral cues are present seems to provide strong evidence for ToM in nonhuman animals. Low-level cues that would be necessary in perceptual state attribution, as the focal individual needs to be able to observe the competitor, are eliminated. The ravens did not have any opportunity respond to such cues but were enacting as if a potential competitor was present. The possibility to observe through a peephole was generalized from the perceptual experience they gained earlier in the experiment. Still, ravens were not able to infer the limited visual angle from the peephole and thus might still be lacking a fully developed ToM.

## Desire States

In common with the attribution of knowledge states, attributing desire states to others requires an ability to acknowledge that others may have mental states that can be different to our own. For example, understanding that although I want prosecco, my colleague may desire tea. A want or desire is not necessarily based on direct behavioral cues although it still can be expressed via behavioral cues.

In an experiment first conducted by Call et al. (2004), chimpanzees were fed by a human through Perspex holes. After initial training, the experimenter stopped to feed the ape either because he did not want to (unwilling) or because he *could* not (unable). Similarly to behaviors of 9-month-old kids (Behne et al. 2005), the chimpanzees showed increased begging and acoustic signaling in the unable condition in comparison to the unwilling condition. Similar behaviors have later been reported in monkeys (Canteloup and Meunier 2017; Phillips et al. 2009) and African grey parrots (Péron et al. 2010). The increased begging behavior in the unwilling condition of these animals has been interpreted as being based on the ability of the subject to understand that the other is not willing to cooperate. Thus, the tested individuals base their own

behavioral response on the current mental state (unwillingness) of the other.

The previous experiment tests whether the focal animal does take the perceptual states of the experimenter into account of its own desire states. Other experiments test whether animals also can take others' desire states into account. A suite of experiments has focused on the desire states of pair partners of Eurasian jays. It has been reported that these birds do adjust their own feeding behavior on the amount of a specific food quality. They will reduce eating the same quality in favor of a different one, independent of their overall satiation level, which is also called specific satiety. Additionally, male pair partners have been observed to attend for the specific satiety level of their female pair-partner. By experimentally manipulating the desire state of the female, male Eurasian jays have been shown to feed the currently most preferred food of the female (Ostojić et al. 2013). Not only do they take into account the desire of their female partner, but also disregard their own current desire state by choosing the food quality the partner prefers but the male is specifically satiated (Ostojić et al. 2014).

Eurasian jays have additionally not only been attentive to specific satiety in a cooperative task – sharing food with their female pair partner – but also in a competitive food caching experiment (Ostojić et al. 2017). Jays were pre-fed a specific food in order to induce specific satiety. Hereafter, jays observed a human experimenter hiding food in a caching tray, to which they subsequently had access. The tested individuals took their own specific satiety into account when pilfering the food caches of the humans; i.e., they pilfered the food that they had not been pre-fed with. Thus, pilfering behavior is influenced by the specific satiety of the pilferer. In the next step of the experiment, caching individuals were allowed to observe another individual being pre-fed with a specific food quality. After observing the pre-feeding of the competitor, cachers were allowed to cache two types of food. They were presented with the food they have observed the other individual eating and an alternative food the observer had no specific satiety for. Caching individuals then preferred to hide the food the observer did not currently prefer

and thereby protect its own caches based on the desire state of the observing individual.

For example Eurasians are sensitive to the desire of the competitor by observing the previous feeding situations and inferring, which food item they would prefer. Similar to the attribution of a knowledge state in the previous section, attributing desires to others seems a strong indicator for ToM especially when no direct behavioral cues are present. Only by integrating their own desire state and the desire state of the competitor, an optimal outcome can be achieved by the caching individual.

## Belief States

In child development theories of beliefs develop much later than children's theory of intentions and desires (Tomasello and Barton 1994). In contrast to attributing desire and knowledge, which both are true or wrong attributions of what the other knows/wants or does not know/want, beliefs can also be wrong. A linguistic version of such a test is the false belief task of Maxi. To attribute Maxi wrongly with a wrong belief or correctly with a wrong belief is an increase of complexity in comparison to attribute him with the knowledge where the chocolate is or is not. So far nonlinguistic versions of the false belief tasks seem the most complex attribution of a mental state an animal has been tested in. Note, some would even negate that animals can instantiate beliefs as they argue that they are based on linguistic abilities.

Coming back to the previous example of knowledge states of Hare and colleagues where a subordinate and dominant individual compete for food (Hare et al. 2001), both individuals observed the initial baiting, but in an additional condition the food was later moved without the dominant seeing. The subordinate had seen the initial baiting as well as the rebaiting. Thus, the subordinate individual has the opportunity to differentiate its own knowledge state of where the food actually is, and represent the false-belief of the dominant. Subordinate chimpanzees showed no increased approach to the food when the dominant was misinformed, which indicates that they were

not able to attribute the false-belief to the competitor, unlike three-year old children in a "Sally-Anne" task.

One of the first experiments in chimpanzees testing nonverbal version of the false belief task was conducted by Call and Tomasello (1999). In this experiment a human experimenter, the hider, hid a food item in one of two containers. After hiding, a second experimenter called the communicator (who had witnessed the hiding), turned and walked away to the end of the room, where he stayed with the back facing the two boxes. As soon as the communicator was in his final position, the hider switched the positions of the containers. Thus, the communicator had a false belief concerning the actual position of the food items and when he later returned marked the box where he believed the food item actually is. The test subjects, great apes as well as young children, were then provided the opportunity to choose one of the two containers; either the one that was marked or the one that they knew contained food. Interestingly, small children were able to correctly choose the unmarked and thus baited box, while orangutans and chimpanzees failed to represent the false belief of the communicator. For many decades, no proof was found that great-apes or any other animal species including corvids can represent false beliefs in a competitive or collaborative food-choice task. By implementing a new methodology of testing false beliefs both great apes as well as 15-month old children (Onishi and Baillargeon 2005) were shown to solve a simplified false belief task. Instead of actually choosing an option, children were tested in a violation of expectancy paradigm. An experimenter and a child saw a toy being placed in one of two boxes. After the initial hiding, the children alone saw the toy being swapped from the initial to the second box. Shortly before the experimenter then had a choice to reach into one of the boxes, 15-month-old children looked more towards the box where the experimenter falsely believed the toy was hidden instead towards the box where the toy truly was hidden. Via this anticipatory looking, it was argued that children younger than 3 years already have a rudimentary theory of mind where they expect

actors to behave based on their beliefs rather than based on their own knowledge. This anticipatory looking experiment was then also adjusted and used in chimpanzees (Krupenye et al. 2016). Similarly, to the task in children, it was for the first time shown that chimpanzees anticipated the behavior of an actor on a screen based on its false belief. This experiment was criticized to be possible to solve via submentalizing (Heyes 2017), which is the prediction of behavior based on low-level, domain-general psychological processes. If this alternative hypothesis is true, children and apes would treat inanimate objects the same way as they do in social interactions between actors. In order to show that the results are not based on submentalizing the same experiment was conducted using colored shapes moving in the same way as the actors in the social condition (Kano et al. 2017; Krupenye et al. 2017). This control confirmed that the chimpanzees do not treat the inanimate condition in the same way as the social condition and thus no evidence was found that submentalizing explains anticipatory looking in the social condition.

Similarly to a previous study by Call and Tomasello (1998), it was therefore confirmed that apes and human children represent the goals or intentions of others. In this earlier test subjects were presented with baited and un-baited boxes. Subjects learned in the training phase to differentiate the baited box via discriminatory cues. In the test phase, a marker was intentionally placed on top of the baited box by an experimenter, while a second marker was accidentally dropped on an unbaited box. Interestingly in this experiment also called the accidental/intentional experiment all tested individuals preferred the baited box that was intentionally marked over the accidentally marked box.

states of con- and hetero-specifics and understand at least in some way the goals of the actions. Whether this ability is a “full-blown” or a minimal ToM (Butterfill and Apperly 2013) is a critical question that has still to be answered in future experiments. Currently it seems that any result can be interpreted at a lower or higher level. Often Occam’s razor is used to argue that the simplest solution tends to be the right one when presented with competing hypotheses (Meunier 2017). It seems important though to provide evidence for choosing one over the other hypothesis, and therefore empirical evidence supporting one of the conflicting theories should be provided making the field of ToM research still one of the most interesting areas of research in comparative cognition. Additionally, it seems more fruitful in both nonhuman animals and human children to regard ToM as a cognitive ability that has gradual differences rather than being present or not. Different species may have differences in the ability of attributing mental states to others in various domains.

To conclude, being able to represent mental states of others increases the complexity of social behaviors and social systems that go beyond behaviors that would merely be based on reading of behavioral cues. Still, none of the conducted experiments has the potential to perfectly discriminate one from the other hypothesis – low-level versus high-level explanation. Promising research areas are to find experimental procedures discriminating “full-blown,” minimal ToM, submentalizing or other lower level explanations in different species. It seems most valuable to additionally test nonhuman animals that have already been shown to have high levels of cognitive abilities like different members of corvids or apes and some species of monkeys.

## Discussion

Based on the discussed experiments on ToM it seems highly plausible that nonhuman animals at least have ToM-like cognitive abilities. They can base their own actions on the basis of a reading of the perceptual, knowledge, desire, and belief
